LABORATORY AIDS IN THE DIAGNOSIS OF ACUTE MASTOID DISEASE DUE TO ACUTE PURULENT OTITIS MEDIA.*

BY GORHAM BACON, M.D.,

NEW YORK.

IN the older works on Otology, pain which was described as being very severe, especially at night, was generally given as one of the most important symptoms of mastoid disease, and it was probably due to the fact that operative interference was not attempted until nature had made an opening through the outer wall of the mastoid bone, producing a subperiosteal abscess which was readily diagnosed as there was marked fluctuation on palpation, the auricle was pushed forward, and the patient in this stage always had an extremely septic appearance. Owing to the fact that at the present time patients are operated upon at a much earlier stage of the disease, pain is not such an important symptom. On the other hand pain is often absent or is only complained of at the commencement of the attack. The patient has a cold, perhaps a sore-throat or tonsillitis, followed by an acute suppurative inflammation of the middle ear. The pain in the ear may be very severe, and there may be a simultaneous tenderness when pressure is made over the mastoid process. After spontaneous rupture of the drumhead or incision of the bulging membrane by the surgeon, the patient may not complain of any further pain except when firm pressure is made over the mastoid bone. In some cases, especially of scarlet fever and diphtheria there may not be any complaint made of pain, and the involvement of the ear may be marked only by a sudden rise in temperature, followed by a bloody discharge from the auditory canal, which comes on very suddenly. In cases of tuberculosis, deafness and a discharge from the ear may be the only symptoms of an acute otitis media. In cases of influenza, especially in children, pain is often absent, and a high temperature with tenderness over the mastoid process, may be the only symptoms of an acute otitis media with simultaneous involvement of the mastoid cells.

It has been so impressed upon the medical profession by the early writers that a patient could not have any serious trouble with the ear, unless there was considerable pain, that it is often difficult for the otologist to convince the family physician that some of the most serious cases are those in which the pain is slight or at times absent. In such cases the infection is apt to be a virulent one.

Very frequently a child will have a slight earache of short duration, accompanied by what is apparently an acute intestinal attack. As the child only complained of an earache for a very short time the case is treated for intestinal disturbance. Calomel is given and the child seems better, but the fever persists, and the physician calls in a specialist who finds a bulging drum membrane with some tenderness over the mastoid cells. Incision of the drumhead, which is followed by a profuse discharge, may terminate in recovery in a short time or what more often occurs, the mastoid bone becomes more sensitive to pressure, and a mastoid operation becomes necessary. In such a case, if the ear had been examined when the child first complained of the slight pain, it would probably have been found that the drumhead was bulging and an early incision would have prevented a mastoid operation.

We frequently see patients who complain of pain which is often quite acute when pressure is made over the mastoid. This either accompanies or follows an acute purulent otitis media. In a few days this tenderness may be extremely slight or it may disappear. The patient says he feels much better, is free from pain, and believes that he is on the high road to recovery. Such a patient generally has a badly coated tongue, a slight elevation of temperature, and examination of the auditory canal will show the presence of a yellowish green and thick muco-pus. Sometimes it is tinged with blood. When we remove the pus from the canal we will find in a few moments that more pus has forced its way through the perforation in the drumhead and that in a very short time the auditory canal will be again filled. This rapid escape of pus, thick in character, which is seen a week or ten days after the onset of the disease, which is becoming more copious instead of diminishing, is a very characteristic symptom of mastoid disease and almost always means that a mastoid operation is imperative. I consider this as the most important symptom of mastoid disease and when present, a patient seldom escapes a mastoid operation.

Another very pathognomonic symptom is a sagging of the posterior and upper wall of the external auditory canal and a bulging of the posterior and upper portion of the membrana tympani.

The temperature in acute suppuration of the mastoid cells is often high in young subjects, especially when the infection is a virulent one.

In adults the patient will often have a temperature of 99.5 at night and it frequently is normal in the morning. A physician who has not had much experience in aural diseases will find it difficult to believe that a patient requires a mastoid operation when he does not complain of pain, and the temperature is only slightly above normal, especially when he makes pressure over the mastoid bone and finds that the bone is not sensitive. Some of the worst cases that I have observed have been those in which pain on pressure was absent. In such

*Read at the 262d regular meeting of the Practitioners' Society of New York, April 3, 1914.

cases we often find the dura exposed and thickened, as well as the sigmoid sinus, which may be covered with granulations—showing the presence of an extradural abscess. The outer wall of the mastoid is often very thick, which may account for the absence of pain on pressure.

Mosher of Boston has devised a transilluminator which is of value in some cases. It consists of an ear speculum closed at both ends but with a window on one side near the tip, through which the rays of an electric light are transmitted. There is an air space about the lamp, so that the speculum heats up very slowly. The patient is taken into a darkened room, the lamp adjusted to its maximum brilliancy, and the speculum inserted into the auditory canal with the window placed posteriorly. It is made to close the meatus firmly so that no light comes through the auricle.

By examining both mastoid processes one can determine whether there is any cloudiness on the affected side.

I believe that the clinical symptoms are always the most important factors in cases of mastoid disease and should give us sufficient information to decide as to the advisability of operative interference. The laboratory, however, has of late years rendered us considerable assistance, and I want to call your attention this evening to the importance of, First, skiagraphy, secondly, the microscopical examination of the pus from the tympanum, and thirdly, daily examinations of the blood to determine whether the leucocytosis is increasing or decreasing, and what relative changes are taking place in the cell percentage. To quote from my text-book, "Skiagraphy is now being extensively used for the purpose of determining whether or not the mastoid is involved and to what extent. This method of examination has proved useful in cases where the clinical symptoms are insufficient for a positive diagnosis of mastoiditis, and is particularly applicable to those cases of furunculosis which simulate mastoid involvement, and to cases of mastoiditis due to the *Streptococcus mucosus capsulatus*, which at a certain stage may present, few if any, clinical symptoms. It gives us advance information of the character of the bone, whether it is of a pneumatic or diploetic type or a combination—the arrangement of the cells; the location of the sinus in the majority of instances, whether it is near the surface or covered with cells, and it will frequently show the size and location of the mastoid emissary vein and its diverticula if any are present.

A series of *x*-ray plates may be of great value in showing an increasing cloudiness due to an empyema or intense inflammation, or the skiagraphs of the mastoid process may become gradually clearer and thus indicate a resolving mastoiditis.

Dr. Dixon, pathologist to the New York Eye and Ear Infirmary, has done a great amount of work in skiagraphy, and in the examination of smears to determine the nature of the infection in cases of suppurative inflammation of the ear and its complications, as well as in examination of blood, including blood cultures. Dixon is able now with the vast experience that he has had, not only to tell us whether there is a cloudiness of the mastoid cells, together with the position of the sinus, but whether in certain cases there are deep cells which contain pus or granulations. I have the reports of a number of operative cases in which skiagraphs were taken before operation, the accuracy of which was verified subsequently when the mastoid cells were opened. An *x*-ray is taken of all cases of mastoid disease at the infirmary in which the advisability of an operation is questioned, and it is particularly in this class of cases that much help can be given us by skiagraphy.

Then, again, an *x*-ray gives us the position of the sigmoid sinus, a most important point because it is sometimes liable to be injured if its course lies close to the antrum.

A good many years ago I asked Dr. Dixon to examine the discharge, microscopically, from the ears of my patients in the infirmary, and this work has been continued ever since with the result that much valuable information has been obtained.

To quote from my book: "During the past eleven years it has been the routine practice at the infirmary to have smear preparations examined in every case admitted to the wards to determine the nature of the infection. Dr. Dixon reports that 5496 such examinations were made during this period, a small proportion being cultivated in unusually interesting and doubtful cases. Of these cases 26.6 per cent. showed a mixed infection, that is, there was a large number of mixed germs, and it was not advisable to assume that the infection was due to any particular germ. The majority of these were chronic cases. In 24.8 per cent. the streptococcus was the predominating germ; in 12.2 per cent. the pneumococcus; in 7.4 per cent. the staphylococcus (aureus and albus); in 4.8 per cent. the *Streptococcus mucosus capsulatus* predominated, while the spirillum of Vincent was found in 1.8 per cent. of the cases. The remaining 22.4 per cent. were miscellaneous, negative, etc., among which were placed the *Bacillus pyocyaneus*, diphtheria bacillus, tubercle bacillus, *B. coli communis*, Friedlander's bacillus, etc. Dr. Dixon has found that the pus taken for examination from the external auditory canal usually shows a mixed infection—that is various microorganisms; but generally the predominating germ is found in the mastoid cells, the sigmoid sinus or brain itself, when these regions are involved. The streptococcus is found frequently in pure culture in cases of infective sinus thrombosis while the microorganisms from the auditory canal may be of the mixed variety. If both the streptococcus and pneumococcus are found in the external auditory canal, we are apt to find these organisms associated in the more deeply seated suppurations, the other microorganisms which may have been present in the discharge from the canal having disappeared.

I quite agree with Dixon when he says that the *Streptococcus mucosus capsulatus* is the most insidious germ the otologist has to deal with. There is apt to be extensive bone destruction when this germ is present. The pain and tenderness may disappear in such cases and the temperature and pulse become normal, but if the discharge persists after two weeks' time, there is grave danger of complications unless a mastoid operation is performed. In cases in which both mastoid processes are opened, it is most important to know the predominating germ because we may have a mixed infection on one side and a virulent streptococcus infection on the other. In such cases when symptoms of infective sinus thrombosis have followed, I have opened the sinus in which the infection was the more virulent and have generally located the thrombus in this way.

Dixon has devoted a great deal of time in the

infirmary to the subject of leucocytosis and has examined the blood in a great number of cases and his conclusions are that in cases of acute otitis media, with mastoiditis as a complication, the leucocytosis ranged from 5,000 to 17,800, and the average polynuclear percentage was within normal limits and that it was not until the more serious complications occurred, such as epidural abscess, sinus thrombosis, and intracranial invasion that the blood count began to have any very marked significance. Important information can be obtained from daily examinations of the blood to determine whether the leucocytosis is increasing or decreasing and what relative changes are taking place in the cell percentage. A most important point to start from would be a knowledge of the normal average leucocyte count and cell percentage in each individual. Impracticable as this may appear, I feel it to be the only rational basis from which to draw conclusions in individual cases.

Dixon read a paper entitled "The Combined Laboratory and *X*-ray Indications for the Mastoid Operation" before the Medical Association of Greater New York on February 17, 1913, in which he speaks of the insidious and destructive character of the *Streptococcus mucosus capsulatus*. He reports six cases of acute suppurative otitis media due to this germ and followed by inflammation of the mastoid cells, which were taken from the records of the hospital, one of them being a patient of mine. These patients all died, five of meningitis and one of brain abscess. According to my experience the most virulent infection is that due to the *Streptococcus mumosus capsulatus*, after that the streptococcus, then the pneumococcus, and lastly the staphylococcus.

In this paper Dixon says "It is not to be understood that the blood count, the form of infection, or positive *x*-ray findings alone can be relied upon to any considerable extent as determining the necessity for a mastoid operation. The clinical symptoms are all important; without them our modern aids are of little value. We may have a rather violent streptococcus infection in the canal, or a pneumococcus infection which looks vicious in the smear, but both may recover after myringotomy, though there may have been considerable mastoid tenderness. In either streptococcus or pneumococcus cases (though we believe more liberty can be taken with the latter, as a rule), the danger signal may be a sudden rise in the polynuclear count, with or without an increased leucocytosis, especially the latter. A positive *x*-ray plate will again settle the diagnosis, though the clinical symptoms may not alone be sufficient to indicate the mastoid operation."

47 West Fifty-fourth Street.

SOURCES OF ERROR IN THE DIAGNOSIS OF PULMONARY TUBERCULOSIS.*

By MAURICE FISHBERG, M.D.,

NEW YORK.

ATTENDING PHYSICIAN, TUBERCULOSIS PAVILION, MONTEFIORE HOME AND HOSPITAL

Scientific investigations depending on careful and exact measurements of concrete facts, areas, distances or certain vital phenomena have shown that human observations are often peculiarly and distressingly liable to error because of inevitable fallacies in observation, measurement and calculation. In fact, there have been devised special methods for the calculation of the so-called "standard deviation," and the "probable error" currently used in dealing with mathematical and statistical facts, be they such as are ascertained by astronomers while measuring rates of motion or distances of heavenly bodies, the size and shape of leaves, stalks, and fruits or other morphological data by botanists, the dimensions of the human body as determined by anthropometrists, or the various vital, social, and psychic phenomena which have been measured with greater or lesser accuracy by the biometricians. Medical diagnosis has not yet reached that stage of perfection as to be considered a science, and the chances of error are consequently greater than encountered in those branches of knowledge which are based on exact mathematical measurement and calculation. It is for this reason that the sources of error are prolific and exact diagnosis depends to a great extent on the personal equation of the clinician, and error is at times unavoidable. In the diagnosis of such an insidious disease as phthisis the errors into which we are liable to fall are almost invariably of such immense importance to the patient as well as to those who have to live and work with him, that a summary review of the causes why we so often fail to recognize this disease in its incipiency, or even in the advanced stages; or why we often believe we have discerned its presence in persons who are not at all tuberculous, may stimulate us in the direction of greater care, judgment and caution before expressing an opinion in doubtful cases and thus reduce the number of diagnostic errors to a minimum.

Of course, when speaking of tuberculosis the active form of the disease, phthisis, is referred to. Infection with the tubercle bacillus is one of the most common of pathological phenomena among modern city dwellers, and it is doubtful whether many escape it. It is also one of the easiest to diagnosticate by means of the harmless cutaneous tuberculin test devised by von Pirquet. A positive tuberculin reaction, which may be found in seventy-five to one hundred per cent. of adults in cities in Europe and America is reasonable proof that the person has been infected with tuberculosis at some time of his life; but it by no means indicates active phthisis, and we must always bear in mind that what we attempt to ascertain is the latter, and not merely infection which is mainly of theoretical importance. That we often fail in our attempts is evidenced by that large contingent of persons of both sexes and all ages who have been told that they were not at all tuberculous but only suffer from mild innocuous "colds," bronchitis, pharyngitis, malaria, gastritis, etc., until they found themselves in an advanced stage of phthisis when treatment is of little avail; and also by the large number of persons who were told years ago that they suffered from tuberculosis, yet without any care or treatment they have been working steadily and feel healthy, often frivolously referring to alarmist doctors who had scared them without any reason. The sources of error in this sort of cases will be discussed in this paper.

The diagnosis of phthisis is often difficult, but more difficult indeed is to decide in many cases when one is not suffering from this disease. It seems to me that by pursuing the inductive or analytic method we are on safer ground when we attempt to discover or exclude phthisis than by

*Read before the Association of Physicians attending the Tuberculosis Clinics of New York City, April 8, 1914.

following the deductive method which is more often used by physicians than it should. By ascertaining the clinical facts of the case the subjective symptoms and the physical signs revealed by exploration of the chest we can, in the vast majority of cases, arrive at a reliable conclusion as to the nature of the process we are dealing with. When we find that a person has been coughing for some time, losing weight and strength, has had fever even of a slight degree, has night sweats and feels fatigued after slight exertion, and also shows signs of a localized and circumscribed infiltration in the lung, we may decide in favor of phthisis. This is a safe decision in most cases, but there are many exceptions in which any or all of these symptoms and signs may be present, yet the person may not suffer from active phthisis as is shown by the subsequent course of the case. On the other hand, not all these symptoms and signs are encountered in many cases of phthisis, or they are not clearly evident and easily overlooked by the patient or his physician, and the result is that the diagnosis is made rather late and the chances of complete recovery are proportionately diminished. Let us see the causes of these errors which are made more often than they should and ascertain whether they are at all avoidable.

Contact Infection.—One of the greatest sources of error in the diagnosis of tuberculosis is a history of contact with a consumptive. It appears that everything has been considered a sign or symptom of tuberculosis excepting the name of the patient and each author has his favorite and infallible criterion for diagnosis, but nearly all agree that when in addition to any obscure and doubtful symptoms there is also a history of exposure the diagnosis is clinched. Now, to my mind this is one of the greatest fallacies we have to cope with. No one living in a large industrial city escapes exposure to infection with the tubercle bacillus, and in fact practically everybody has been infected as is evident from data brought out by the most delicate of tests for infection, the tuberculin reaction which only rarely fails. The ubiquity of the tubercle bacillus is even greater than is generally appreciated. It is, however, a traditional dictum among physicians to accuse all those who have lived with consumptives of being sick with phthisis. As regards infants there is great justification for alarm, but it is different with adults who have surely been infected during childhood and reinfection is known to be exceptional, perhaps impossible, and a history of exposure is of no value and is no criterion of morbidity. This is best proven by a consideration of persons who are most exposed to infection through intimate contact, such as husband and wife. The fact is that marital phthisis is relatively scarce, which tends to point to some form of immunity acquired through constant and intimate association with consumptives. It also appears that physicians, nurses, and hospital attendants in sanatoria and hospitals for consumptives, are no more liable to suffer from phthisis than other classes that only rarely come in close contact with tuberculosis. This is true not only at present when precautions are taken to prevent infection in sanatoria, but was already observed some forty years ago by C. Theodore Williams at the Brompton Hospital, and used as an erroneous argument against the transmissibility of tuberculosis. It is, therefore, erroneous to pronounce a widow, whose husband died from tuberculosis, as phthisical without valid clinical evidence, as has been the rule among those who are active in the campaign against the white plague. In this city I find it very often difficult to convince persons who have been exposed to infection that they are not sufferers from phthisis. The least cough or debility scares them to an unreasonable extent, and they are supported as a rule by physicians as soon as they give them a history of exposure.

Sources of Error in Bacteriological Diagnosis.—The diagnosis of active tuberculosis is clinched by the finding of tubercle bacilli in the sputum, but is not at all excluded by negative bacteriological findings. Unfortunately too many wait rather long for the bacilli, thus losing valuable time which can not often be reclaimed by any known means. I find this one of the most common fallacies in the diagnosis of incipient tuberculosis. We must always bear in mind that tuberculosis begins as an infiltration of the peribronchial tissues which may remain for a long time beneath the mucous membrane of the bronchi, and it is thus clearly evident why the sputum may not contain any bacilli for a long time, till the lesion is quite advanced, when caseation and softening has taken place and the products of tissue disintegration are eliminated by breaking through a bronchus. In many cases waiting for tubercle bacilli in the sputum is as hazardous as waiting for pus to make its appearance through a fistula or sinus before diagnosing tuberculous joint disease.

From the theoretical, and especially from the statistical standpoint, the finding of tubercle bacilli in sputum is a sure indication of active phthisis, and among thousands of cases the number in which this is not the case is undoubtedly small and insignificant. But with an individual patient, as we deal with in our offices or clinics, even in this there may be a source of error which is hardly ever mentioned while discussing the problem. In New York City we meet with many persons who have reports from some private, or the municipal laboratory, stating that the sputum of the bearer has been examined and found to contain tubercle bacilli. Yet, without any treatment or special care, they have kept at work for years and felt well. Indeed, many cases are admitted to sanatoria solely on the strength of positive sputum findings to be declared non-tuberculous after careful clinical observation. The reason for this anomaly is to be sought for in several facts which have not been emphasized as strongly as they should. I have no doubt that many cases in which the sputum was examined in a busy laboratory there may have occurred some mistake in handling the sputum bottles, in numbering the slides, or while entering the findings in the report. Laboratory workers are human, and even with the most conscientious care which they usually exercise they are liable to err, just as bank clerks occasionally do, though the latter find their mistakes as soon as they attempt to add up their columns, while laboratory workers may never know of an error committed. But in addition there are other sources of error in the examination for acid-fast bacilli. The rod-shaped bacillus which is the cause of tuberculosis is not the only acid-fast microorganism we know. There are many others which, on staining, simulate the tubercle bacillus to an extreme degree. They are found in butter, milk, on graminacea, in the soil, in dung and manure, and even in tap water supplied through metal pipes. We may recall the search

for tubercle bacilli in the blood of consumptives that has been going on during recent years, and that some bacteriologists have discovered the bacilli in fifty to one hundred per cent. of tuberculous, and also in a large proportion of apparently healthy persons. Other investigators have, however, found the sources of error in these cases. Walter V. Brem has shown that the acid-alcohol resisting organisms were found eventually in fresh distilled water, in tap water, in old distilled water made with care in a pathological laboratory. These microorganisms were dead or non-pathogenic to guinea pigs, but they gave the usual staining reactions. Then we have the smegma bacillus, which has been mistaken for the tubercle bacillus, and led to erroneous diagnosis and extirpations of healthy kidneys. There is also the acid-fast lepra bacillus and the bacilli which greatly resemble it and found in the secretions of the mucous membrane of the nose, and also the acid-fast rods found in the saliva and in the secretions in cases of bronchitis and pulmonary gangrene.

In a recent communication Dr. L. Napoleon Boston reports on finding tubercle bacilli in sputum of acute colds and influenza with disappearance during convalescence. In the cases observed by him careful physical examination failed to disclose positive evidence of a pulmonary lesion, although the signs of acute bronchitis were more or less well marked in each case. Many showed a greater tendency toward violent irritation of the nasal mucous membrane than they did of the bronchial tract. In some instances the sputum was slightly tinged with blood. They all made rapid and apparently permanent recoveries.

Many of these microorganisms are difficult to differentiate from tubercle bacilli microscopically, through culture and even by animal inoculations. It has also been found that the spores of lycopodium are acid fast, so that persons taking pills covered by that substance may impart some to the sputum and thus lead to error. There is a possibility that the acid-fast specks or rods found in sputum may not have been there before it left the bronchial tubes and trachea, but got into the sputum while it was passing through the pharynx, mouth, or lips, especially in a house inhabited by a careless consumptive. It is also important to mention a striking fact that ordinary smear preparations are less likely to lead to this sort of error than the antiformin method.

To be sure, the most reliable sign of phthisis is finding of the bacilli in the sputum, and I do not at all intend to underestimate its significance. Statistically the chances of error just mentioned are undoubtedly insignificant. But as has already been stated in the individual case, especially when the course of the disease is not such as would be expected in phthisis, it is of immense importance to bear in mind that an error may have crept in somewhere.

Abortive Tuberculosis.—In many of these cases we actually deal with active pulmonary tuberculosis which ran an abortive course. The notion that phthisis is invariably a progressive disease, running a certain course, variable within certain limits and terminating in death, or, when timely and properly treated, in recovery, is erroneous. There are more cases that are aborted within a few months than those which pursue the usual acute or chronic course which we are wont to consider phthisis, as is evident from the enormous number of persons dying from any cause who show healed lesions at necropsy. I have no doubt that in many cases in which we believe that our diagnosis of active tuberculosis was rendered doubtful by the mild and short course of the malady and the prompt recovery of the patient, we have dealt with abortive tuberculosis of which I have spoken in detail elsewhere.

Tuberculin.—In sanatoria, after all the available means of diagnosis have been exhausted, or even before, tuberculin is used to clear up doubtful cases, and the outcome of this test is considered specific. Personally I have never been impressed with this diagnostic agent. From the scientific standpoint we are far from having sufficient and satisfactory proofs to speak with certainty about the cutaneous tuberculin test and its underlying causes, and from the theoretical standpoint, its specificity has not been proven conclusively. The cutaneous tuberculin reaction is admittedly of little value as a diagnostic agent for active tuberculosis in individuals over two years of age. It also appears that other toxins, such as that of typhoid, cholera, dysentery, etc., give the same skin reaction in tuberculous individuals as tuberculin. Conversely, there are records of autopsies in which the reaction was positive during life and no macroscopic tuberculous changes could be found in the body.

The subcutaneous tuberculin reaction has also been found to lead to erroneous conclusions in some cases. In a recent collective inquiry in Germany most of the replies were to the effect that many cases of active tuberculosis are met with in which the reaction is negative, and *vice versa*. In addition, it must be mentioned that the heightened susceptibility of the tuberculous to suggestion plays a great rôle, and that an injection of water, *injectio vacua*, may give a typical tuberculin reaction with fever, malaise, aching of bones and joints, etc. F. Kohler found that 21.7 per cent. of his tuberculous patients responded to the *injectio vacua* in the same manner as to tuberculin, and Lorenz and others have confirmed this observation. On the other hand, it has been found that five to ten per cent. of persons clinically free from active tuberculosis give positive reactions to the tuberculin test. It is thus evident that we are not justified in relying implicitly on the results of the tuberculin test when attempting to clear up a doubtful case. Considering that it is by no means devoid of danger, it is clear that it should not be used as often and indiscriminately as it has been.

Hemoptysis.—When we consider the subjective symptoms of tuberculosis which are liable to mislead, we must always bear in mind that hemoptysis is one of the most unreliable symptoms of this disease, although a great clinician once said that it is always of tuberculous origin unless proven to be caused by some other condition. But it is just because the vast majority of hemoptyses are of tuberculous origin that when it is derived from some other source it may at times prove a strong source of error. I need not dwell on the cases in which it is due to bleedings from the nose, throat, gums, or stomach, which are quite frequent; nor need I more than mention that acute inflammations of the trachea and larynx may be accompanied by blood-tinged sputum, and that the blood may be derived from angiomata of the esophagus. But I shall emphasize the frequency with which we meet hemoptysis in cases of organic heart disease, espe-

cially mitral stenosis. Inasmuch as these patients are often emaciated, cough, and occasionally run mild fever, the diagnosis of tuberculosis is at times made erroneously. It is, in fact, usually supported by some physical signs in the lungs, because many cardiacs show some defective resonance, alteration of breath sounds and even râles at one apex. I have seen numerous patients suffering from organic heart disease who are cared for in the tuberculosis clinics and day camps in this city. This source of error can, as a rule, be eliminated by carefully examining the heart in each case and bearing in mind that while tuberculosis is not entirely excluded in cases of heart disease, it is extremely rare, especially in mitral stenosis.

Hemorrhages in cases of bronchiectasis are also a cause of error in diagnosis, and it is often very difficult to differentiate between bronchiectasis and advanced phthisis. I have been guided by the general nutrition of the patient, relying on the fact that a large proportion of bronchiectatics are fairly well nourished, while the tuberculous having such extensive involvement of the lung with so many large consonating râles are cachectic and run a hectic type of temperature. But even this is liable to mislead because we have occasionally cases of phthisis in which the panniculus adiposis is quite well preserved, or with marked and annoying obesity. Other points in differentiating these conditions are that the sputum in tuberculosis is only rarely fetid and usually contains tubercle bacilli, while in bronchiectasis it is often extremely malodorous and is evacuated periodically in large quantities. Syphilis of the lungs is also at times accompanied by hemoptysis. The Wassermann reaction is of some assistance in diagnosis which is very difficult in many cases. In syphilis the lesion is usually localized in the lower lobes, and the dyspnea is severe, out of proportion to the extent of pulmonary involvement. In most cases the therapeutic test alone can decide—an extensive process clearing up after the administration of a dose of salvarsan or mercury for a month.

Fever.—Active phthisis, even in its very incipiency, is accompanied by fever, and it may be laid down as a rule which has few, if any, exceptions that if there is no fever there is no active tuberculosis. But when we attempt to elicit the fever in incipient cases we are often misled to a perplexing degree. In nearly every case of incipient tuberculosis we find a subfebrile temperature during the afternoon or evening. The elevation of temperature may be of only one or two degrees, but it can be found if carefully looked for, and in many cases some subnormal temperature may be found during the early morning hours. Measuring the temperature in these cases, if not done methodically, is open to many fallacies. It must be taken at least every three hours, because when taking it only three times a day we are apt to fall into the grave error of pronouncing a patient free from fever, when in fact he has had a subfebrile temperature which escaped our attention. Thus there may be a rise of one or two degrees at two o'clock in the afternoon which fades away within two or three hours, and when we take the temperature only at about 7 A.M., 12 M., and 6 or 7 P.M., we may find it normal. In such cases, if the temperature had been taken every two hours we would have found that at 5 to 7 A.M. it was subnormal, 96.5° F. to 98 F., while at 2 to 5 P.M. it was 99.5° F. to 100° F. There may also be rise of temperature exclusively during the night, and thus remain undiscovered. Other sources of error in suspicious cases of phthisis are bad thermometers, which are more frequent than good ones, and the taking of the temperature in axilla, or mouth. The ways to avoid these fallacies are obvious. In my experience intelligent patients may be entrusted with taking their own temperature and keeping a record of each reading in a note book. I have had some patients who gave me reliable data for plotting temperature curves from figures representing thermometrical readings every two hours for weeks, and very often this has been of great assistance in clearing up doubtful cases, and arriving at a conclusion much earlier than I could had I not temperature curves representing thermometrical readings every two hours.

We are, however, apt to fall into error when we rely solely on the slight elevations of temperature for a diagnosis of tuberculosis without localizing the lesion in the chest. Thus, many cases of chlorosis and other blood diseases show a slight elevation of temperature in the afternoon, or after moderate exertion. Purulent diseases of the accessory sinuses of the nose and chronic infection of the tonsils may act likewise, and so may ulcer of the stomach, syphilitic disease of the liver, exophthalmic goiter, chronic inflammations of the female pelvic organs, and last, but not least, bronchiectasis, etc.; they may all show slight fever which is not unlike that of active tuberculosis.

Percussion.—It is thus evident that the diagnosis of tuberculosis should only be made when we have definite signs of a local lesion in the lung, and this can only be done by careful and conscientious physical exploration of the chest and with the aid of radioscopy. But here also there are many sources of error which must be borne in mind, especially in doubtful cases.

Differences in the resonance elicited when the two sides of the chest are comparatively and symmetrically percussed, especially in its upper third, are the best indications of airless pulmonary tissue in the less resonant area. But to make a diagnosis of an active tuberculous infiltration with this sign alone would be sheer madness in a large proportion of cases. Thus we may have differences in resonance, when the two sides of the chest are compared, due to faulty technique of percussion, also because of asymmetry in the contour of the thorax, in cases of kyphosis, or scoliosis, or unilateral hypertrophy of the muscles. Dull areas must also be properly interpreted if we want to avoid errors. Chronic pneumonic processes, healed apical pleurisies, and especially collapse induration caused by the inhalation of dust in persons affected by mouth breathing may be mistaken for tuberculosis. The last is so often a cause of error that one must be on his guard when finding signs of airless lung tissue in the right apex and not be too ready in making a diagnosis of incipient tuberculosis. We also find occasionally dullness in the apices among persons leading a sedentary life, particularly chlorotic girls who do not breathe deeply, and for this reason a good way to reduce the chances of error to a minimum is to make the patient breathe deeply for several minutes and also to practise Da Costa's method of respiratory percussion, which often clears up a case otherwise obscure.

Percussing the apices we must also remember that only infiltrations located superficially can be demonstrated by this method of examination, and

that small airless areas surrounded by normal lung tissue do not impair resonance; in fact, they may impart a tympanitic quality to the percussion sound. The percussion stroke does not penetrate deeper than six centimeters into the chest, and from this is to be deducted some two or three centimeters making up the parietes, so that the percussion blow reaches only three to four centimeters deep into the lung. It is thus obvious that centrally located infiltrations can not be made out by percussion, and in cases of emphysema the difficulties are even greater, at times invalidating this method of exploration. Some lesions are surrounded by vicariously emphysematous lung tissue and escape detection, while disseminated tubercles relax the lung tissue and may produce tympany. This can be seen in many incipient cases in which the lesion is centrally localized at one apex, or better still, in acute miliary tuberculosis in which the tubercles are scattered all over both lungs and the resonance all over the chest is tympanitic. In fact, we often meet with cases in which apical percussion reveals no deviation from the normal, yet auscultation, sputum examination, symptomatology, and course of the disease all combine to show that we are dealing with an undoubted case of active tuberculosis.

Radiography.—Radioscopy, while of immense importance, and often giving clues as to pathological processes in the lungs which could not be elicited by any other diagnostic procedure, is subject to just as many chances of error as percussion. Both radioscopy and percussion, when carefully performed and interpreted, show localized areas of airless tissue. In the former it is shadows and mottling that indicate the affected areas, and in the latter defective resonance and dullness in an area that normally should be as resonant as the opposite side of the chest betrays the affected spot. But we are not always justified in assuming that these airless areas are due to tuberculous infiltrations. The chest showing no shadows suggestive of pulmonary or glandular lesions on the roentgenogram has hardly been met. Persons clinically free from pulmonary disease often show on the radiogram shadows and mottling exactly like those of active pulmonary tuberculosis, which is to be expected considering that the *x*-ray picture discloses not only active pathological changes in the thoracic viscera, but also traces of all the changes that have taken place in these organs during the lifetime of their owner. It is also a fact that early tuberculous lesions, slightly enlarged bronchial glands, unless caseated or calcified, as well as mucous secretions, usually permit the rays to pass through without casting any shadow on the plate. On the other hand, optical sections of blood vessels, due to any condition that may cause vascular engorgement, may show opacities on the plate simulating those characteristic of tuberculous lesions and may thus lead to error. Even when the airless areas revealed by the roentgenogram have been caused by a tuberculous process we are not justified to conclude invariably that the disease is active, because healed lesions in the lung, unless covered by emphysematous tissue, remain less resonant on percussion than normal lung tissue, and permanently show shadows on the radiogram. Whether a lesion, discovered by percusion or radiography, is active, can only be determined by a careful consideration of the accompanying symptoms and signs of the disease.

Other sources of error in radioscopy of the chest are: Asymmetry of the thorax due to spinal deformities and the differences in the intercostal spaces resulting from them; unequally developed muscles on the two sides, enlarged breasts in women and occasionally in men, etc., all of which may show shadows on the radiogram which are not due to pathological processes in the lung proper. It is also precarious to consider all shadows and mottlings in the region of the hilus as caused by enlarged tuberculous glands because there are other conditions which may be responsible. To mention but few other sources of error, it must be always borne in mind that we may find shadows in the upper part of the lung which are not due to tuberculosis, but to simple atelectasis, acute non-tuberculous pulmonary indurations, and also collapse induration, as well as compression of the apex by an enlarged thyroid, etc.

Auscultation.—Auscultation, which is the method of exploration of the chest mostly resorted to and relied on by physicians, is subject to erroneous interpretation to the same extent as any other diagnostic method. In incipient tuberculous lesions the changes in the breath sounds and the adventitious sounds encountered, to be of significance, must be localized and persistent for some time. Evanescent râles, unless accompanied by important signs and symptoms, are, as a rule, of no significance. When we hear changed breath sounds and râles scattered all over the chest the chances of it being of a tuberculous nature are rather slight, though not invariably excluded. Tuberculosis implanted in a chest affected by general bronchitis, or pulmonary emphysema is difficult, often impossible to diagnose without positive sputum findings. The localized tuberculous process can not be delineated and differentiated because it is obscured by the large number and variety of adventitious sounds heard all over the chest. But even unilateral lesions are apt to be misleading. There are simple, non-tuberculous apical catarrhs, especially after attacks of influenza, in persons with pulmonary emphysema, or who are of poor muscular development, particularly women, and among individuals engaged in indoor and dusty occupations. I have recently been impressed that in a large number of persons working in dusty workshops, inhaling animal and vegetable dust, the breath sounds at the right apex are harsh, the expiratory murmur prolonged, often of a bronchovesicular or even bronchial character. Among several hundred apparently healthy tailors, furriers, carpenters, etc., that I have examined annually during the past ten years, I found that about fifty per cent showed such changes in the auscultatory phenomena of the right apex in various degrees. When such persons are attacked by influenza, rhinopharyngitis, tonsillitis, etc., and run a mild fever for several days, cough, expectorate, etc., and a careful physical examination is made, a fallacious conclusion is apt to be drawn, and tuberculosis of the right apex diagnosed or suspected.

There are other sources of error which must be guarded against while auscultating the chest with a view of determining the absence or presence of phthisis. We often miss adventitious sounds because the bronchus leading to the site of the lesion is plugged up by secretions and we may thus get feeble or even absent breathing in the affected area. Inducing the patient to cough vigorously may clear up the condition, but not always. On the other hand, we may hear râles which are altogether of extrapulmonary origin. This is often the case with

persons who suffer from nasal obstruction, and making the patient breathe through the mouth while we auscultate the chest may change the condition. A frequent cause of extrapulmonary râles is the falling back of the tongue when the patient makes strong efforts to breathe deeply; also after vigorous coughing the patient swallows and we believe we hear râles in the chest.

Other extrapulmonary râles, described by Peretz and Ewart in England and Bushnell in this country, are caused by muscular contractions, especially the trapezius, and on raising and lowering the shoulders and arms. French authors speak of "*craquements et frottements sous-scapulaires*," which can be heard very often over the upper part of the chest posteriorly. Then we have the so-called atelectatic, and marginal râles heard over the anterior and lower margins of the lung and which are probably caused by the unfolding of collapsed alveoli in individuals who breathe superficially, and also by the peeling off of the diaphragm from the chest wall as the lung descends into the complemental space. Bushnell also describes sounds originating in the sternum and its articulations and heard particularly at the second costal articulation which may lead to error, and I have been able to verify his findings in a large number of healthy persons, especially muscular men. In some cases they resemble crepitation, and occasionally even medium-sized moist râles and clicks, like the adventitious sounds of phthisis. They can usually be distinguished from pulmonary râles by the fact that they are localized and heard loudest over the sternum and its articulations, but in doubtful cases, especially in those showing a short note at one apex, they may lead to error. Recently there have been described râles heard over the acromion as an infallible sign of incipient tuberculosis, and carefully searching for them, I found that they are of the "extrapulmonary" variety, of the same character and origin as the sternal sounds just mentioned, and are heard in many healthy people. This again illustrates one of the sources of error in the diagnosis of phthisis.

Conclusion.—Errors in the diagnosis of active tuberculosis can be avoided when we always bear in mind that there is no single symptom or sign which is pathognomonic of this disease. The most reliable criterion for diagnosis is undoubtedly the tubercle bacillus, but in some cases even this may lead us astray, and recently, since the antiformin method is extensively used, the number of errors of this character has enormously increased. In cases showing tubercle bacilli in the sputum, but in which careful clinical observation discloses no symptoms of phthisis, there is always a possibility that some other acid-resisting microorganism has been mistaken for the tubercle bacillus. With the antiformin method of sputum examination, errors of this kind are more liable to be committed, and a single examination of the sputum showing but few bacilli is to be taken with considerable reservation unless the symptomatology and course of the disease is that of phthisis.

The signs revealed by physical exploration of the chest, as well as radioscopy, are indicative of the physical condition of the thoracic viscera, particularly the air content of the lung, and at times anomalies of the chest wall obscure the picture and may lead to error in findings and interpretation. Percussion and radioscopy may show us airless areas in the lung, or enlarged and calcified thoracic glands, but whether these processes are of tuberculous origin or, if so, whether the lesion is active, these methods can not decide in each case. Auscultation reveals interference with the entry and exit of the air stream through the bronchi and air vesicles, but whether we are dealing with changes caused by the tubercle bacillus and if so whether the process is active and progressive, or merely an old scar, or calcified nodule, auscultation can not decide in every case, and at times may lead to error. Even râles, which are excellent proof of activity of the process in the vast majority of cases, must not be invariably considered as of pulmonary origin. In doubtful cases it is advisable to guard against extrapulmonary râles before pronouncing a patient tuberculous. To avoid error we must always bear in mind that there are nontuberculous apical catarrhs caused by the pneumococcus, the streptococcus and the influenza bacillus, and also collapse induration of the right apex in mouth breathers, all of which show local signs simulating tubercle of the apex. Error in judgment and fallacy in reasoning can best be avoided by correlating all the subjective and objective symptoms and signs elicited at several examinations and assigning each one its proper place and value before drawing conclusions.

1337 Madison Avenue.

WILLIAM WITHERING AND HIS BOOK ON THE FOXGLOVE.

By Louis Kolipinski, M.D.,

Washington, D. C.

In writing of the history of digitalis in medicine it is proper to introduce the subject with a biographic sketch of the physician whom a fortunate accident and a clear and correct judgment guided in the proper use of the drug. His book upon it is a model for medical observation and its value today is the same as when written, barring the advancement in chemistry and pathology, in therapeutics and practice. These have extended and amplified our knowledge, they have detracted nothing from the correctness of the original description of the action and value of the remedy in impairment of the vascular circulation.

Thus Wm. Cullen in his "Treatise on the Materia Medica" (3rd American Edition, 2 vols., 1808) does not describe digitalis or foxglove at all, but says: "I can direct my reader to a more proper means of instruction by referring him to the treatise of my very ingenuous and learned friend, Dr. Withering, on this subject, which is a treatise in many persons' hands and in my opinion should be in the hands of every practitioner of physics."

William Withering* was born March 17, 1741, at Wellington, in Shropshire, England. More anciently the family name was written, Witherings, Widdrington, or Witherington. His father was a practitioner of physic. The same profession being chosen, he was matriculated at the University of Edinburgh, 1762. His first medical essay, "Topical Bloodletting," was written in 1764, and in the same year his first treatise, "Inflammation of the Pericardium," upon which Cullen bestowed an encomium. He wrote further: "Commentary on the Aphorisms of Hippocrates"; "Dissertation on Dropsy"; "Treatise on Rickets"; "A History of Angina Inflammatoria." His inaugural dissertation was upon "Malignant Putrid Sore Throat."

*"Miscellaneous Tracts of William Withering by His Son," two volumes, 1822.

He received the degree, Doctor of Physic, July 31, 1766. Thereupon he made a trip to Paris of which he said that it "was not deficient in medical science; in surgery it was unrivaled."

He married in 1772 and began practice, but "his professional engagements scarcely produced, on an average of six years, one hundred pounds per annum." He then left Stafford for Birmingham to succeed Dr. Small. In 1776 his practice and receipts increased so that he soon had an income of a thousand pounds a year. Ill health began to appear and he became the victim of an irregular fever.

He published: "A Botanical Arrangement of All the Vegetables Growing in Great Britain According to the System of the Celebrated Linnæus; with an easy introduction to the study of Botany." Two vols. Next came "Bergman's Essay, De Analysi Aquarum." He engaged himself in the chemical analyses of natural waters and became a member of the Lunar Society with men like Dr. Priestly and Messrs. Boulton, Keir, and Watt. This was one of the best private philosophical clubs in the kingdom.

He aided the completion of the general hospital at Birmingham. At his own house on stated days he gave gratuitous advice to the poor. His extensive practice caused him to travel day and night. Whilst on such journeys he read and wrote. On winter nights for such purpose he had a light in his chariot. Thus he prepared among other works, "An Account of the Scarlet Fever and Sore Throat or Scarlatina Anginosa, particularly as it appeared at Birmingham in the year 1778."

He became an active member of the Society for Promoting the Abolition of the Slave Trade. In the winter of 1783 he suffered from a severe pulmonic affection.

His next work was a translation of Sir Torbern Bergman's Sciagraphia Regni Mineralis under the title, "Outlines of Mineralogy." In the Philosophical Transactions appeared, "Experiments and Observations on the Terra Ponderosa." He discovered aerated barytes or carbonate of barytes. The native barium carbonate is named after him *witherite*. In 1785 he published his celebrated "Account of the Foxglove and Some of Its Medical Uses, with Practical Remarks on Dropsy and Other Diseases." This was published at this time, his biographer says, because of the possibility of being anticipated by other claimants to whom he had taught the use of it; especially the endeavors of one physician who most unfairly attempted to arrogate the discovery to himself.

In this same year he was made a fellow of the Royal Society and received a diploma from the Medical Society of London. With increasing fame his house was a resort of intelligent and educated travelers. His income from his medical practice reached two thousand pounds per annum. In 1787 appeared a new edition of his "Botanical Arrangement." A new genus of plants *Witheringia solonacea* was named after him by L. Heritier de Brutelle.

He was consulted medically from remote parts, patients coming from London, Paris, and from different places in Britain and Ireland. Amongst other celebrities came Benjamin Franklin, the American philosopher. In the spring of 1790 he suffered from peripneumony, and the next year had still another attack.

Withering had a tolerable facility in writing Latin and in reading Greek. He held the dead languages to be vehicles of knowledge. For the medical profession he advised the study of Celsus. Upon the drink habit he most aptly wrote: "Those who have been only a few years in medical practice become aware that by far the greater number of diseases which embitter and cut short our existence are the effect of intemperance in strong liquors; nor does there seem much difference in the choice of them."

In 1791 he was made a Fellow of the Linnean Society. In 1792 he went to Portugal for his lung trouble, as the South of France, a preferable climate, was then much disturbed. Of Portugal as a health resort he said, "perhaps the climate of Portugal may rather be deemed inefficacious than unfavorable in consumptive cases." Of pulmonary consumption he wrote: "And not many medical men are sufficiently aware that phthisis is contagious. Though some writers positively deny that phthisis pulmonalis is infectious the contrary fact is to me indisputable."

In 1793 he made a second trip to Portugal for the sake of his health. Whilst there he wrote a memorial on the caldos water, a physical and chemical examination of which he presented to the Royal Society of that state. In 1794 his health grew worse, he had inflammatory lung attacks, dyspnea, and repeated hemoptysis. He grew incapable of general practice and engaged in writing and in botanical studies.

In 1795 his health improved.

In 1796 he issued the third edition of the "Arrangement of British Plants" in 4 vols.

In 1797 and 1798 his illness grew worse, he was so dyspneic that writing was difficult. He died October 6, 1799, after twenty years of sickness, aged 58. His death was tranquil; after being dressed he said, "Now I am ready."

The nature of Withering's long sickness was then chronic bronchitis and bronchiectasia, not primary tuberculosis; if tuberculosis was present at all it was implanted upon the chronic process in the bronchi.

The full title of the book on digitalis is: "An Account of the Foxglove and some of Its Medical Uses with Practical Remarks on Dropsy and other Diseases by Wm. Withering, M.D., Physician to the General Hospital at Birmingham. Birmingham, 1785. In the original edition is the motto from Horace: "Nonumque prematur in annum."

In the preface he gives the reason for the publication. "The use of the Foxglove is getting abroad and it is better the world should derive some instruction, however imperfect, from my experience than that the lives of men should be hazarded by its unguarded exhibition or that a medicine of so much efficacy should be condemned and rejected as dangerous and unmanageable."

A good botanical description of the plant is given concluding which is said: "This plant ranks amongst the Luridæ, one of the Linnean order in a natural system. It has four congeners, Nicotiana, Atropa, Hyoscyamus, Datura Solanum, etc. So that from the knowledge we possess of the virtues of those plants and reasoning from botanical analogy we might be led to guess in some degree at its properties. The plant has a bitter taste but not a nauseous one, as declared by others." To his knowledge it has been mistaken for mullein (Verbascum.)

Withering's attention was attracted to digitalis in the following way: "In the year 1775 my opinion was asked concerning a family receipt for the cure of the dropsy. I was told that it had long been kept secret by an old woman in Shropshire who had sometimes made cures after the more regular prac-

titioners had failed. I was informed also that the effects produced were violent vomiting and purging; for the diuretic effects seemed to have been overlooked. This medicine was composed of twenty or more different herbs; but it was not very difficult for one conversant in these subjects to perceive that the active herb could be no other than Foxglove.

As further introductory is inserted an historical view of the properties of digitalis by Dr. Stokes of Stourbridge. These notes are very short and cursory, but very interesting and of much importance. The principal subjects are therefore here presented more properly and fully from the original sources.

The following is the title page and the description of Foxglove from the folio on medicinal plants of Leonhard Fuchs of Tuebingen: De Historia Stirpium Commentarii insignes, maximis Impensis et Vigiliis *Elaborati*, adjectis earumdum vivis plusquam quingentis imaginibus nunquam antea ad naturæ imitationem artificiosius effictis et expressis Leonharto Fuchsio medico hoc nostra ætate longe clarissimo Autore. Basileae, Anno Christi *MDXLII*. By the publisher; Sequentia duo capita quoniam absoluto ferme opere ad nos venerunt et idcirco suo loco reponi non potuere tamen ne lector iis fraudaretur in calcem potuis rejicere quam omnino praeterire, collibuit.

De Digitali. Cap. CCCXLII. Nomina. Digitalis. Quod appelatione tum Græca tum latina herba hæc hodie destituta sit, nulla alia de causa factum existimamus, quam quod veteribus incognita fuerit Nos pulchritudine eius anonumom esse diutius non sumus *passi*. Appellabimus autem Digitalem, alludenter ad germanicam nomenclaturam. Fingerhout sic enim Germani hanc stirpem nominant a florum similitudine, quæ digitale pulchre referunt ac exprimunt. Hac appellatione utemur donec nos vel alii meliorem invenerint.

Genera. Digitalis purpurea. Digitalis lutea. Duum est generum una enim purpureos obtinet flores ideoque Digitalem purpuream appellavimus. Germanis brauner Fingerhut dicitur. *Altera luteos* habet flores ob id Digitalis lutea dicta nobis est. Germanis geeler Fingerhut nominatur. In aliis per omnia similes sunt.

Forma. Herba est cubitalis foliis latis et oblongis, Plantagini non dissimilibus, in extremitatibus serratis floribus a lateribus caulis ordine dependentibus, digitalis formam referentibus, purpureis out luteis. Quibus decidentibus, semen in calycibus latum et oblongum profert. Radix illi est exigua et capillata.

Locus. Nascitur in montibus, umbrosis et saxosis locis.

Tempus. Floret Julio potissimum mense atque subinde cadentibus floribus semen producit.

Temperamentum. Impense amara est herba perinde atque Gentiana ut hoc nomine calidam et siccam esse evidentissimum sit.

Vires. Haec herba haud dubie quum opus est extenuatione, abstersione, purgatione et obstructionis liberatione, efficax admodum esse solet. Nam ut testatur Galenus libro iiii de simpl. med. facul. cap. XVII Amari sapores abstergunt, expurgant et quæ in venis est crassitiem incidunt. Quamobrem menses etiam quæ amara sunt movere possunt et ex thorace et pulmone pus educere. Quid multa potest hæc herba fere omnia quæ Gentiana cujus vires suo in loco invenient studiosi.

That digitalis was unknown to the Ancients is generally believed. What records are available as testimony are here appended. No writer has been found in modern medical literature who asserts that this evidence is anything but uncertain.

Pedanii Dioscoridis Anazarbei, de medicinali materia libri Sex, Joanne Ruellio Suessionensi interprete. Francofurti 1549, lib. iii Cap. XLII.

Baccharis. Baccharis herba fructicosa quæ in coronas additur, cuius folia aspera sunt media violæ et verbasci magnitudene: caulis angulosus cubiti altitudinem empetens aliquantulum asper, non sine appendicibus adnatis: flore purpureo, subalbicante, odorato: radicibus veratro nigro similibus, quibus odor inest cinnamomo proximus. Asperum squalidumque solum amat.

Radix in aqua decocta ruptis vulsis, ex alto præcipitatis, spirandi difficultati, salutaris *item* diutinæ tussi et urinæ difficili; menses pellet contra serpentium morsus utilissime datur in vino. recens radix opposita partum extrahit; puerpesis eius decoctum in deffessionibus prodest. In diapasmata utiliter inseritur, jucundi odoris gratia folia utpote quæ adstringast, capitis doloribus illitum prosunt. oculorum inflammationbus mammis tumentibus a partu ægilopiis incipientibus ignibusque sacris auxiliantur. odor somnum gignit.

Nomina et Explicatio. Nostrates officinæ Baccharim non norunt. Rura apud Gallos diuæ Mariæ chirotecas. Germani unser frawen hendtschuch appelant eamque nectum in coronas, Baccharim esse facile potest intelligi cum fructicosa sit herba, cuius folia quandam referunt asperitatem media violæ verbascique magnitudine, caule anguloso cubiti altitudinem petente, agnatis appendicibus *quandam tenus* scabris, flore purpureo, subalbicante, radicibus nigro veratro similibus, cinnamomum subolentibus asperum *squalidumque* solum amat. Paulus odoratam esse tradit herbam, odore cinnamomum imitantem quam coronis dicari soleat. Bacchare fascinum depelli *Virgilius* autor est; ita canens:

baccare frontem
Cingite, ne vati noceat mall lingua futoro

Quidam hanc herbam pro Chrysogono *habent* Germanice *Benedictenkraut*.

C. Plinii Secundi, Naturalis Historiæ, lib. XX. 16.

Bacchar quoque radicis tantum odoratse est quibusdam nardum rusticum appelatum. *Unguenta* ex ea radice fieri solita apud antiquos. Aristophanes priscæ comœdiæ pœta testis est. Unde *quidam* errore falso barbaricam eam appellabant. Odor est ei cinnamomo proximus; gracili solo nec humido provenit. Simillimum ei, combretum appellatur, foliorum exilitate usque in fila attenuata, et procerius quam bacchar. Nec hæc sunt tantum; sed eorum quoque error corrigendus est, qui bacchar rusticum nardum appellavere; est enim alia herba sic cognominata, quam Græci asaron vocant, cujus specien figuramque diximus in nardi generibus. Quin immo asaron invenio vocitari quoniam in coronas non addatur.

Lib. XXI. 77. Bacchar in medicinae usu aliqui ex nostris perpressam vocant. Auxiliatur contra serpentes, capitis dolores fervoresque; item epiphoras. Imponitur mammis tumentibus a partu, et ægilopis incipientbus, et *ignis sacris*. Odor somnum gignit: Radicem decoctam bibere, spasticis, eversis, convulsis suspiriosis, salutare est. In tussi vetere radices ejus tres quatuorve decoquuntur ad tertias partes. Hæc potio mulieres ex abortu purgat. Laterum punctiones tollit, et vesicæ calculos. Tunditur et in diapasmata. Vestibus odoris gratia inseritur. Combretium, quod simile ei diximus, tritum cum axungia vulnera mire sanat.

The note to Chapter 16 in the English translation of Pliny's history by Bostock and Riley, Vol. IV, p. 318, is as follows: Fee is inclined to coincide with Ruellius and to identify this with the Digitalis purpurea, Clown's spinard or our Lady's Gloves. The only strong objection to this is the fact that the root of the digitalis has a very faint but disagreeable smell and not at all like that of cinnamom. But then, as Fee says, we have no positive proof that the cinnamomum of the ancients is identical with our cinnamom. Sprengel takes the "bacchar" of Virgil to be the Valeriana celtica and the "baccharis" of the Greeks to be the Gnaphalium Sanguineum, a plant of Egypt and Palestine. The Bacchar has been also identified with the Asperula odorata of Linnæus, the Geum *urbanum* of Linnæus (the root of which has the smell of cloves), the Inula *Vaillantii;* the salvia sclarea and many other plants.

John Parkinson, apothecary of London and the King's Herbarist in his great work "Theatrum Botanicum," London, 1640, thus described digitalis purpurea vulgaris:

The Virtues. The Italians have an usuall proverbe with them concerning this herbe called by them Aralda, which is *aralda*, tutte piaghe salda; aralda selveth all sores; for they use it familiarly to heale any fresh or greene wound or cut, the leaves being but bruised and bound too, and sometimes also they use the juyce in old sores to clense them, dry up their moysture, and heale them the more speedily, which it performeth by the bitter quality therein whereby it is found to be healing and drying and clensing withall; so that whensoever there is neede of a rarefying or extenuating of thicke tough plegme and viscous humours troubling the chest or stomacke; the decoction or juice hereof made up with some sugar or honey is available, as also to clense and purge the body both upwards and downwards sometimes of tough plegme, and clammy humours and to open the obstructions of the Liver and Spleene; and yet notwithstanding that these qualities are found to be in it, there are but few Physitions in our times that put it to these uses but is in a manner wholly neglected. It hath been found by late experience to be available for the King's Evil, the herbe bruised and applyed to the place, or the juice made up into an ointment and used thereon: And it hath beene of later experience found also to be effectual against the Falling Sickness, that divers have been cured thereby; for after the taking of the decoction of two handfulls thereof with foure ounces of Pollipody, of the Oake bruised made in Ale, they that have been troubled with that disease 26 yeares and have fallen once in a weeke or two or three times in a moneth have not fallen once in 14 or 15 moneths, that is untill the writing hereof which I think may be sayd to be an absolute cure not to be presumed that after so long stay it should returne againe.

Amongst the earliest experiments with the poisonous properties of Digitalis are those of Salerne of Orleons. Hist. de l'Acadam., 1748, p. 84. This one amongst others: A turkey-cock of 7 pounds was given half a handful of the chopped leaves mixed with bran in the space of four days. It began to droop, refused to eat more of it. Its excrement was like a dysentery. It had convulsions. Death took place on the eighteenth day. Its weight then was three pounds. "On opening him," Stokes quotes, "we found the heart, the lungs, the liver, and gall-bladder shrunk and dried up; the stomach was quite empty, but not deprived of its villous coat."

Withering said he used digitalis at first in his dispensary practice, but the dose he gave was too large and continued too long. After the cure of Dr. Cowley of Oxford University of hydrops pectoris by an empirical exhibition of the root of the foxglove after some of the first physicians of the age had declared they could do no more for him, he thought the use of a root of a biennial plant uncertain and he continued to use the leaves and was determined to pursue his former ideas more vigorously than before. He found the dose of the leaves to vary with the seasons and to be most constant in the flowering state. The more he saw of the great powers of the plant the more it seemed necessary to bring the doses of it to the greatest possible accuracy.

He thought a decoction might be carelessly made or its properties impaired by long boiling. The infusion was therefore substituted for it and after this he also used the leaves in powder.

He perceived that its diuretic effect is not dependent on nausea or vomiting; if the medicine purges, he said, it is almost certain to fail in its desired effect. He saw it succeed here with small doses of opium.

Digitalis was admitted to the Edinburgh Pharmacopœia of 1783 on the recommendation of Dr. Hope. Withering regretted that at that time in the medical practice of London and Edinburgh doses too large were given. In his hands the plant did little service in phthisis pulmonalis, although he desired to make further use of it. It was a domestic remedy of the common people in the west of England for this disease. Withering records the histories of the patients treated by him with digitalis in the years 1775-1785, being one hundred and sixty-three. They are all of interest to a practitioner and Case IV may be an example.

Withering examined Mrs. H. of 40 or 50 years, July 25, 1776. Her sickness began about June 4, since which time she was treated by Dr. Darwin. A chill and fever, a pain in the left side, shortness of breath, and persistent cough; after some days copious expectoration. Withering found her nearly suffocated, with a weak and irregular pulse, breath short and labored, arms leaden in color, clammy, and cool; she could not lie down; had much thirst; stomach, legs, and thighs swollen; the urine small in quantity, being passed a spoonful at a time.

Scarification of the legs was not acceded to. He hesitated at first to recommend digitalis as the case was one so unfavorable. However with Darwin's consent he prescribed:

Fol Digital purp. recent ℥ iv.
Coque ex. Aq. fontan. puræ lb. iss ad lb. i. et cola.
R. Dicoct Digital, ℥ iss.
Aq. Nuc. Moschat, ℥ ii M. fiat haust.
2 dis horis sumend.

The patient took five of these draughts which made her very sick and acted powerfully upon the kidney, for in 24 hours she passed upwards of eight quarts of water.

July 26. Our patient thus snatched from impending destruction.

August 1. Free from dropsy, breath easy, still very weak.

September 17. The dropsical symptoms made it necessary to repeat the digitalis. After nine years the patient relieves herself whenever she chooses with digitalis infusion. Since the first exhibition

of that medicine very small doses have been always found sufficient to promote the flow of urine.

Further is published the histories of more cases treated with digitalis by fifteen correspondents; of these, Jones in Lichfield reports twenty-four cases which the author arranges in a form of disease and results, thus:

Anasarca, 7 cases, 3 cured, 1 relieved, 3 failed.

Ascites, 5 cases, 4 cured, 1 relieved.

Odematous leg, 1 case, 1 cure.

Ascites and Anasarca, 7 cases, 4 cured, 2 relieved, 1 failed.

Asthma and Dropsy, 1 case, 1 failed.

Hydrothorax and Dropsy, 1 case, 1 cure.

Hydrothorax, Ascites, and Anasarca, 2 cases, 2 cured.

Withering's book ends with the section, entitled "Practical Remarks on Dropsy and Some Other Diseases," which record his opinions of the actions and effect of digitalis in diseases as understood with the scant knowledge of pathology of his time. His reasoning and judgment, however, are those of a skilled and practical clinician.

Anasarca is generally curable in the subcutaneous cellular tissue or in the substance of the lungs. Ascites, without anasarca in children, is curable, in adults, generally incurable by medicines. Ascites and anasarca are incurable in diseased viscera or old gouty constitutions; in other situations it is curable In cases of ascites, anasarca, and hydrothorax one can get relief only. True spasmodic asthma is not relieved by digitalis. Asthma and anasarca, if the affection of the breath depends upon cellular effusion, are curable. Epilepsy, dependent on effusion, is curable. Hydatid dropsy is incurable. In hydrocephalus (meningitis) digitalis is uncertain in its effects.

Withering thought the effusion originated in inflammation. His case LXIX, was probably one of cerebrospinal meningitis. Master Whaet, aged 6, treated with bleeding, daily mercurial inunction into the legs, and later infusion of digitalis, with recovery. Hydrothorax and dropsy of the pericardium, with intermittent pulse and pain in the arm, are curable with digitalis. Hydrothorax and anasarca are curable. In insanity digitalis does good. Case XXIV, with recovery, was one of delirium tremens. Case XXXIV, a young puerpera with anasarca of legs, was also cured. (It was puerperal mania.) Ovarium dropsy defies the power of medicine.

In late ovarian dropsy with anasarca digitalis gives relief for a time. In phthisis pulmonalis with anasarca or hydrothorax, digitalis relieves suffering, but Withering saw no good results from it in consumption. In puerperal anasarca digitalis gives an easy and certain cure.

Of the preparations and doses of the foxglove, Withering preferred the leaves to the root, stem, flower, or seeds. He rejected the leaf stalk and midrib of the leaf which he dried in the sunshine or before a fire. A beautiful green powder was obtained, one-fifth of the original weight. An adult was given 1 to 3 grains of the powder twice a day. In a reduced state of disease 4 grains a day were enough. As a liquid, one dram of dried leaves was infused for four hours in one-half pint of boiling water and one ounce added of any spirituous water. The medium dose for an adult was 1 ounce twice a day. If the patient was strong and the symptoms very urgent the dose might be given once in 8 hours; but in many instances half an ounce at a time would be sufficient. About 30 grains of the powder or eight ounces of the infusion could generally be taken before the nausea commenced.

The following were his remarks on the effects, rules, and cautions: "The foxglove when given in very large and quickly repeated doses, occasions sickness, vomiting, purging, giddiness, confused vision, objects appearing green or yellow; increased reaction of urine with frequent motions to part with it and sometimes inability to retain it; slow pulse, even as slow as 35 in a minute, cold sweats, convulsions, syncope, death. (Note, I am doubtful whether it does not sometimes excite a copious flow of saliva.) Even in a less violent manner it produces most of these effects in a lower degree and it is curious to observe that the sickness with a certain dose of the medicine does not take place for many hours after its exhibition has been discontinued; that the flow of urine will often precede, sometimes accompany, frequently follow the sickness at the distance of some days and not infrequently be checked by it. The sickness thus excited is extremely different from that occasioned by any other medicine, it is peculiarly distressing to the patient; it ceases, it recurs again as violently as before and thus it will continue to recur for three or four days, at distant and more distant intervals."

He thus details his own improvements regarding its use. He first thought sickness necessary for the diuretic effect, and patients were directed to persist till nausea came on and then stop, but it was found diuresis might occur first, so the direction was changed to continue the medicine till the urine flowed or sickness or purging took place. After some years he found cases where the only effect was an alarmingly slow pulse, so he amplified the directions: "Let the medicine be given in the doses and at the intervals mentioned till it acts on the kidney, stomach, pulse, or bowels; let it be stopped upon the first appearance of any of these effects. If it purges it seldom succeeds well. Patients should drink freely as they are very generally prepossessed with an idea of drying up a dropsy by abstinence from liquids and fear to add to the disease by indulging their inclination to drink. . . . From some cases which have occurred in the course of the present year I am disposed to believe that the digitalis may be given in small doses, viz., two or three grains a day, so as gradually to remove a dropsy without any other than mild diuretic effects and without any interruption to its use until the cure be completed." For its poisonous effects he thought that an antidote might in time be discovered. He found cordials and volatiles were usually rejected, but aromatics and strong bitters were longer retained. Brandy would remove slight sickness. He thought small doses of opium sometimes useful, but felt more confident of the advantages of blisters. He held the constitution of the patient unfavorable to the helpful aid of digitalis in men of great strength, tense fiber, warm skin, florid complexion, and light and cordy pulse; also in cases of tense and circumscribed ascites, solid, and resisting anasarca.

He tried to change the constitution of the patient by blood-letting, neutral salts, crystals of tartar, squills, and occasional purging but succeeded imperfectly. Next in power to the lancet to lower the tone of the system, he said, is squill "consequently it will always be proper in such cases to use squill, for it is one of the best preparations to the adoption of the digitalis. Tendency to paralytic affection, stroke of palsy, or stone in the bladder is no objection to the use of digitalis."

Withering submits these inferences upon the uses of digitalis: "(1) Digitalis will not universally act as a diuretic. (2) It does so more generally than any other medicine. (3) It will often produce this effect after every other probable method has been fruitlessly tried. (4) If this fails there is but little chance of any other medicine succeeding. (5) In proper doses it is mild in its operation. (6) When dropsy is attended by palsy unsound viscera, great debility, or other complication of disease, neither the digitalis nor any other diuretic can do more than obtain a truce to the urgency of the symptoms; unless by gaining time it may afford opportunity for other medicines to combat and subdue the original disease. (7) The digitalis may be used with advantage in every species of dropsy except the encysted. (8) It may be subservient to the cure of diseases unconnected with dropsy. (9) It has a power over the motion of the heart to a degree yet unobserved in any other medicine and that this power may be converted to salutary ends."

In the third volume of medical transactions published by the College of Physicians in London, 1785, is the account of the successful use of the foxglove in some dropsies and in pulmonary consumption by Erasmus Darwin, with an appendix by Sir George Baker narrating a case in which it was used. These papers confirm the good effects from the use of digitalis in cardiac dropsy. Its good action is doubtful in the other diseases related. These productions are of some amusing interest as they make it plain that Darwin was unfriendly to Withering and Sir George likewise both to Withering and the foxglove. Darwin does not mention Withering. Sir George says: "As a remedy for a dropsy this plant seems to have been but of late introduction. But at what time and by whom, it was first given in this disease, it has not, I believe, hitherto been ascertained." In a note to a second appendix by Baker, he says of Withering's book that it was a numerous collection of cases. "To these cases the ingenious author has added some instructions respecting the use of this plant which claim our attention; for a substance possessing so extraordinary and peculiar a power over the motion of the heart, if administered by the hand of ignorance and inexperience, is in its effects much more likely to be a poison than a remedy."

As the foxglove is a biennial plant, wrote Darwin, it may be procured fresh at all seasons of the year. He made use of a decoction. Four ounces of the fresh leaves in two pints of water are boiled down to one pint and two ounces of vinous spirit added. Dose, a tablespoonful every hour till from three to eight or nine are taken or sickness produced. The hydropic fluid disappeared on the second or third day without repetition of the medicine, frequently without apparently increased evacuations, at other times with vomiting and large flow of the urine and sometimes with purging stools.

To more robust patients he gave a spoonful and a half of the decoction or two spoonfuls. In some patients two or three times relieved by the same method in the space of from six to ten months, a lesser quantity was found to succeed. In consumptives and in cases of scrofulous ulcers half an once of the decoction of digitalis was administered twice a day for many weeks.

In a pamphlet with the title, "Experiments establishing a criterion between mucoginous and purulent matter with an account of the retrograde motion of the absorvent vessels," 1780, printed for Codell of the Strand, Darwin subjoined half a dozen cases of dropsies treated successfully by the decoction of digitalis. Now he adds a score of other cases of dropsy, the seat of which is supposed to be in some part of the thorax and which is attended with anasarca of the limbs.

The patients here attended to had in general passed the meridian of their lives, and had habituated themselves to too great a quantity of fermented or spirituous liquors. Many of them had previously been subject to the gout, and had a considerable degree of corpulency. They had in general edematous swellings of the legs and thighs, great difficulty of breathing, and very unequal pulse. Some of these patients had experienced no return of the disease from the first day of their having taken the medicine; many of them had three or four times in the space of two years been obliged to have recourse to the same method, generally in lesser quantity than at first and with the same success; that is, their difficulty of breathing and the swelling of their limbs vanished in one day or two; and their pulse became much less irregular; but Darwin said he did not recollect that in those where it was very unequal it ever returned to perfect equality; which gave reason to suspect that the disease was not radically cured, and was therefore more liable to recur after some weeks or months. The following cases, grouped by classes, were reported by Darwin:

1. Dropsies of the Thorax and Limbs: Three cases, antecedent gout; men of 45 to 60 years.

2. Dropsies of the Abdomen: Three cases and two others without record. The author recommends its further trial in dropsies of the ovarium and in ascites and also in hydrocephalus internus.

3. Pulmonary Consumption: One case cured; a shoemaker of 20, apparently with febrile consumption for two months. One tablespoonful or one and a half tablespoonfuls of the decoction given twice a day until recovery.

4. Scrofulous Ulcers: A young woman of 20, pale ulcer on each external ankle. Five to ten grains of the powder of the dried leaf were given twice a day and a bandage applied. Cured. In the second case, also a woman of 20, ulcers were present on the neck, cheek, sternum, arm, and other parts, oozing thin matter. The decoction twice daily nearly finished the cure in two months.

5. The common or humoral asthma with distressful breathing at night helped by use of the decoction.

6. Melancholia. A miss of 30 to 40; the despondency of her mind gradually wore off in a few weeks after nausea and vomiting had been produced by digitalis.

The case of Sir George Baker was a gentleman of 60, with anasarca and dyspnea who was at first relieved by a bolus of five grains each of purified quicksilver and fresh squills taken every second night. Growing worse he was encouraged by Darwin's experience to make a trial of the decoction of foxglove. He took a tablespoonful of it every hour for three doses. In twenty-four hours he passed six quarts of urine, his pulse fell from 90 and 120 to 54 and 60 a minute and was very irregular. He obtained great relief. In a few weeks the dropsy returned. Later he took the powder in one grain pill, but one or two a day. The dropsy again disappeared and his breath was not oppressed when quiet. His body and limbs were every day well rubbed, and to this operation he partly attributed his recovery. He died a few months later, the disease returning and the foxglove being taken without avail.

A woman servant of this gentleman had pain in the abdomen, shortness of breath, edematous legs, nausea, and scant and turbid urine. She took a one-grain pill of digitalis powder twice a day, until she had used thirty-one. The pulse from the beginning became slow and irregular. The nausea and all the other symptoms ceased. In two cases of ascites, one treated with the decoction, the other with the pill, the medicine failed in both cases.

Darwin also aimed to make the medicinal virtue of foxglove immortal by means of poesy, singing thus:

Bolster'd with down, amid a thousand wants,
Pale Dropsy rears his bloated form, and pants;
"Quench me ye cool pellucid rills," he cries,
Wets his parched tongue and rolls his hollow eyes.
So bends tormented Tantalus to drink
While from his lips the refluent waters shrink;
Again the rising stream his bosom laves
And thirst consumes him mid circumfluent waves.
Divine Hygeia from the bending sky
Descending, listens to his piercing cry;
Assumes bright Digitalis dress and air;
Her ruby cheek, white neck and raven hair;
Four youths protect her from the circling throng,
And like the Nymph the Goddess steps along.
O'er him she waves her serpent wreathed wand,
Cheers with her voice and raises with her hand
Warms with rekindling bloom his visage wan,
And charms the shapeless monster into man.

Botanic Garden. Part 2. Canto. 2.

PSYCHOLOGICAL ASPECTS OF THE RELATION OF DIVORCE, ACCIDENTS, CRIME, ETC., TO MENTAL DEFECTS.*

A PRELIMINARY REPORT.

BY SIEGFRIED BLOCK, A.M., M.D.,

BROOKLYN, N. Y.

THE purpose of the paper is to show some of the psychological connections between mental deficiency and divorce, alcoholism, insanity and personal accidents, and especially death resulting from these accidents. That illegitimacy is a cause of mental defect is at present quite well established. There is no doubt that defect of mentality is hereditary, that such bodily affections as phthisis and syphilis may in some manner be associated with this inferiority. That alcohol and perhaps some other drugs have a definite connection with mental defect cannot be denied. Which is the cause and which the effect depends in a goodly measure on the individual case, but the writer believes an absolutely normal individual will practically never become an habitué of any drug.

With the acceptance of these premises the writer first wishes to take up briefly the problem of divorce in general, from the viewpoint of the psychologist. Separation, desertion, and divorce proper are included in the term under discussion. Practically every case of the character mentioned is the result of a long time of quarrel, disagreement, and unhappiness on both sides. When two persons cannot be made to realize that to come to terms is for their mutual benefit, particularly when they must appreciate that their causes of differences are trivial in character, enlarged only by association with other and graver matters, some defect of reason, or faulty judgment, perhaps, may be at the bottom of the whole trouble.

*Read before a conference on psychology, at Columbia University, April 8, 1914.

That weakened judgment is hereditary is to be accepted without proof. Suffice it to say that defects of mentality are positively inherited, according to Galton, Davenport, Prince, Cattell, Ellis, Lombroso, Goddard, Barr, Forel, Wundt, etc. In the high types of mental defect even when the defect is not superficially evident to friends and relatives, judgment must be affected. Judge Nash, of the Domestic Relations Court, in discussing this subject with the writer, said that he was seeking a woman to do some darning and mending by the day at his home and of all the cases that came before him he found it almost impossible to find any woman capable of doing this practically simple kind of work, although in every case these women claim they are down and out. On the face of such facts inferiority must be acknowledged. That divorces run in families can hardly be denied. The writer has personally gathered statistics of twenty-four such families. No general statistics are so far available on this matter.

In general the causes for coming to a Domestic Relations Court are desertion, non-support, brutality, incompatability, bad habits of one or the other party, as alcoholism, etc. In most of the cases of non-support, the underlying factor is inability to support. This at once characterizes the person as deficient mentally. If a person cannot agree with his life-partner on account of a bad habit, such as alcoholism, mental abnormality must be acknowledged, at least on the part of the habitual drunkard. Gross immorality is one of the points of diagnosis in the discovery of abnormal mental status. In the same way real brutality, if it is grave enough to appear in court as a proposition by itself, may suggest perversion. Crime is never a cause for divorce, yet each one of these twenty-four families has criminals, mental defectives, etc., on one or both sides of the house. The writer will briefly give the histories of two of the families and a short description of the trouble between man and wife to show that heredity is an element to be reckoned with:

CASE I.—S., male, albino, sent to me for a diagnosis of his mental condition. On investigation this is the family history: Father's mother, a periodical drunkard; the husband of this woman separated from her. One sister of the father was separated from her husband. The maternal grandparents separated. The parents separated; the mother charged her husband with bigamy. This boy was feebleminded and epileptic; his mother's sister was epileptic and mentally deficient. This boy met with two serious accidents in life. When twelve years of age an iron column fell on his left heel and he was in a hospital; at thirteen he had a compound fracture of his left hand due to a fall. This will be taken up later.

CASE II.—This case shows a frequent type of disagreement between man and wife. Both parties are highly moral, educated, refined, and cultured people. The writer has known the family for four years. In the beginning there was only a spat now and then. The husband was an excessive whiskey drinker. Then came arguments about his drinking too much; these were justifiable. Then he began to make less money and the wife was unhappy. She quarreled more and he became more stubborn and, although he stopped drinking for months at a time, both developed a hatred for each other. Finally they did not talk, and could not live together, and he became lax in his obligations. She saw a lawyer. The three children were told the father was no good. A new gentleman became interested in the family's welfare, etc. Although the writer brought these two factions to an understanding for weeks at a time the patchwork was only temporary. Arguments like these were presented, "You only buy me nice clothes so that you can go out with a well-dressed woman." "In other words, you do not supply

me for my sake, but for your own sake. You are very selfish."

This case, which seems to be a simple one, has also an antecendent history. It was related to the writer that the mother of this woman nagged her husband, that they were finally divorced, and that a second husband lasted only a short time, when he also was separated from his wife. The husband's mother became a widow very early. One of the children was distinctly abnormal. The father has met with several accidents and one of the children has had her finger partly amputated as the result of an accident.

The faulty judgment here shown is quite typical of many cases and should be more thoroughly studied psychologically. Like every other case that I have in the list of twenty-four, this case came to me on account of a mental examination that was desired for some member of the family.

One of the main causes of divorces, etc., are the prostitutes. Lombroso and others have classed these people midway between normal and criminal types, if there are such types. Almost every observer to-day classes them for the most part as degenerates, regarding them at best as morons. The class of people who disregard marriage laws because they do not care for society or its institutions, and act as they wish regardless of what their relatives or acquaintances may think of them, may be regarded as of the same type as the anarchist who carries out his dogmas by means of bombs, fire, etc. Some are actually insane, others are defective. Mock marriages, rash unions, and unions for lustful reasons, are all liable to be of short duration and the parties to such life contracts do not fully appreciate what they do. The District Attorney's office in New York City is opposed to going far for deserters and bringing them back, their principal argument being that the men are usually not worth the expense.

Before closing this subject, the writer desires to emphasize his conservative attitude with regard to these two propositions, which are daring to say the least. It is true that the institution of divorce is a blessing many times for those concerned. These ideas are based on the facts that cases which come up before the Domestic Relations Court often have the same motives as those coming up before the higher courts. In the State of New York, in all the other States, and in all civilized countries, actual separations and divorces can be obtained only from the highest courts. The expenses of these trials with the preliminary fees, etc., are so great that the masses find it almost impossible to avail themselves of the privilege. It is, therefore, rather unscientific to consider only actual divorces in a paper such as this. It is always difficult to enumerate the defectives among the wealthy, but even in these cases, if proper examinations could be made, it is likely that parallel results would follow. The vast amount of statistics regarding mental defectives is practically a compilation of masses and not of classes. Individual cases hardly count, especially when both parties are not submitted to a mental examination.

A study of accidents is very close to a study of reaction-time. When a person does not know whether it is better to go backward or forward in order to avoid an accident and gets caught for the mistake, it may mean that he has not responded quickly to a stimulus which surely was important to the individual concerned. To take hazard risks is not always a sign of mental deficiency, but to take such a chance without careful forethought is a sign of lack of judgment. This is putting it mildly. If an unfinished building is in the way and a sign for danger advises everyone to cross the street to avoid falling timber or bricks, and one person gets hit who takes a chance, and does not obey, such a person is a fool or a moron. The best proof of this is to go through the wards of any emergency hospital and look over the patients who have been picked up by the ambulances. After we omit the alcoholics, who we know in most instances are below par, and then cut out those in whom positively slow reaction was responsible for the accident, we will find very few patients left. This is the reason why accident insurance companies, as the "Travelers'," etc., have such low rates. The largest proportion of their customers are average or better and take few chances. Even such instances as accidental shootings, or of being shot for someone else, etc., can be proven to indicate a tendency toward degeneration in many cases. For example, the association with persons who would be likely to shoot another, or the act of playing with a dangerous weapon without proper precautions, suggests inferiority.

One of the most interesting points in this comparison is that the same individuals meet with frequent accidents. The rule on questioning persons who have met with a serious accident is to find that they have had at least another accident. It is interesting to note that in many cases at least one other member of his or her family also met with some accident. In fact, heredity plays a very strong part in a series of twelve cases I have enumerated It is interesting that in so many cases where divorces are common in families accidents occur frequently. If we add epilepsy, crime, and mental deficiency we get a group which can be found in a majority of the members of certain families. It simply means that certain traits were inherited in these cases, traits such as weaknesses, negative characteristics. In prisons it is estimated that between 25 and 80 per cent. of the inmates are known to be feeble-minded. A large proportion have deserted or divorced the rest of their families. An astounding number of convicts have scars showing previous accidents. The pictures in the rogues' galleries prove this. In institutions for the feeble-minded practically all the inmates have scars.

It must be remembered that separate courts have been designated to take care of marital disputes on account of the enormity of the problem. Like mental defectives the calamity is on the increase. My groups are far too small to provide important statistics, but nine mothers, nine fathers, five brothers, and three sisters of people (twenty-four) who were examined as to their mental condition have had family disunion to a marked degree. Likewise of 112 persons interrogated in four semi-private hospitals, forty-six had had a previous accident and thirty-two had had more than one serious previous accidents, and twelve had near relatives who had been in hospitals on account of some injury. The regular city and county hospitals were not taken into account because it is quite evident that a large percentage of their population is always below the average mentality. These varied statistics have been obtained from the German, St. Catherine's, the Jewish and the Long Island College hospitals. The writer cannot at this writing remember a single case out of a possible 40,000 or 50,000 examinations in which an undoubted defective did not have a scar from some accident. Of eight automobile owners who hire chauffeurs, the

writer has inquired if any had reckless chauffeurs, and without exception on discussion they agreed that such drivers were not quite normal, taking a chance without forethought or purpose. This kind have most accidents.

848 Greene Avenue.

CAUSE AND PREVENTION OF PYORRHEA ALVEOLARIS AND FURUNCULOSIS

By F. TWEDDELL, M.D.,
SUMMIT, N. J.

Pyorrhea alveolaris is not a new disease. It has existed in all ages and attacked men of all nations. It is not influenced by climate, nor is it limited to any particular type of human being. The jaws of the ancient Egyptians, of the Assyrians, and of other Orientals are said to show undoubted evidence of it. It is very prevalent in carnivora, especially in old age, but I have not been able to discover whether herbivora are ever affected by this disease.

In looking over the medical literature on the subject, one is positively bewildered at finding nearly every conceivable disease or condition put down as a cause for pyorrhea alveolaris. Here are some of them: heredity, constitutional disorders or debility; thermal, chemical or mechanical changes, whatever these may mean; irregular and crowded teeth, stomatitis, oral catarrh, chronic nasal catarrh, gingivitis, mouth-breathing, uncleanliness, irritating deposits, skin eruptions, gout, rheumatism, tuberculosis, nephritis, syphilis, diabetes, "lung affections," malnutrition, luxury, nervous debility or defect in innervation, minute organisms, indicanuria, sanguinary calculus, frequent pregnancies, amenorrhea, dysmenorrhea, paretic dementia, locomotor ataxia: certain metals and salts, *e.g.*, mercury, sodium, phosphorus, lead, lime, common salt, "uratic salts," and so on. I could add more to this long list, but it is unnecessary. It would have redounded to the credit of the dental authorities to have said in plain English: "We do not know the origin of this disease," for that is what it amounts to after all. No doubt pyorrhea alveolaris has often been associated with some of the above diseases or conditions, but that is a different matter.

We know, however, that there are many otherwise healthy persons who are afflicted with Riggs' disease, which would incline us to believe that it is due to faulty metabolism. Mercury, potassium iodide, lead and the constitutional diseases of rickets and scurvy profoundly affect the teeth and gums, but we know how to deal with such cases as soon as we can ascertain the cause.

Talbot reports that 33 per cent. of the children with rickets are sufferers from Riggs' disease. These children are constitutionally below par and they are consequently far more liable to infections than healthy children.

A specific germ has not yet been demonstrated. Talbot has shown that pus from dogs infected with pyorrhea alveolaris injected into the gums of healthy dogs did not produce the disease, which is another proof of faulty metabolism. The tissues of healthy dogs therefore contain some substance which resists this particular type of infection and this substance evidently is deficient in dogs afflicted with pyorrhea alveolaris. What is this substance?

The treatment for Riggs' disease so far has been almost entirely mechanical, *i.e.*, scraping of the roots of the teeth, applications of the tincture of iodine to the gums, antiseptic mouthwashes, prophylactic toothbrushes. Some authorities have prescribed tonics. Once started, the disease usually gets worse, the patient suffers more and his visits to the dentist become more and more frequent. In the end the teeth become so loose that they have to be removed. Sometimes a splint is applied to a loose tooth to try and save it, but this is only of temporary benefit. Autogenous vaccine has given very poor results, for the simple reason that the pus from which it is made is a local manifestation of a faulty metabolism, as I shall show later on.

I shall now describe the means by which I arrived at the conclusion that pyorrhea alveolaris is due to faulty metabolism, owing to the deficiency of a certain substance in the blood, the supplying of which promptly checks the pyorrhea.

Four years ago I had occasion to treat a case of recurring boils. Autogenous vaccine, large amounts of yeast, and calcium sulphide had been given thorough trials, but apparently without result. In despair I prescribed plain powdered sulphur, one heaping teaspoonful three times a day after meals. The laity have used it from time immemorial to "purify the blood," and evidently for very good reasons. After its administration the infiltrated area of the boil became circumscribed, and if not discharging pus, shrank, and was gradually absorbed. No more boils appeared whilst the sulphur was taken. In the case of a boil discharging pus the astringent action of the sulphur was noticed, the inflamed area became restricted and its tissues contracted, forcing out the pus. The cavity healed up far more rapidly than after an incision. Boils not discharging required no dressing, those discharging needed only a simple clean dressing.

The numerous trials I gave sulphur were sufficient to convince me that it was effective in every case. The only objection to it was its bulk and sandy feeling in the mouth. I knew of no liquid preparation of sulphur in the pharmacopeia that might take its place. Thinking the matter over carefully I came to the conclusion that sulphur taken internally is assimilated to a certain extent through chemical action of the body fluids, and that possibly sulphur trioxide (SO_3) is thus formed and absorbed by the blood.

Now, sulphur trioxide is one of the inorganic salts of the blood and exists both in the plasma and the corpuscles. The only sulphate said to be present in the blood is that of potassium. The feces contain the sulphates of sodium and calcium and we are told that sulphuric acid is excreted in the urine. Indican is also a sulphate. Sulphuric acid taken internally would probably split up as follows: $H_2SO_4 = H_2O + SO_3$.

Realizing this chemical action I gave sulphuric acid a trial and found its action far quicker and more effective than sulphur. Using the diluted sulphuric acid, I ordered from thirty to sixty drops, diluted in two to three ounces of water, three or four times a day, the mouth to be well rinsed immediately after. The effect on boils and carbuncles in every case was astonishing, the astringent action being wonderful. Within twenty-four hours marked changes for the better were noted.

Since sulphuric acid has such a favorable action on boils, we cannot but come to the conclusion that furunculosis is due to a hematogenous infection, perhaps through the oropharynx. The old and hitherto accepted and unchallenged etiology, *i.e.*, infection through a hair follicle or sebaceous gland,

is to my mind no longer tenable. The latter is only a local manifestation of serious metabolic changes. We often see furunculosis and abscesses in cases of malnutrition and diabetes, which are not due to a local but a hematogenous infection. There can be no question about this. Uncleanliness and dirty surroundings do not bring about furunculosis; on the contrary we find this disease exists mostly, perhaps entirely, in those persons who are of cleanly habits, but in poor health, overworked, dissipated, or subject to much worry and anxiety, and I might perhaps add, those who are deprived of proper physical exercise and fresh air.

Does a deficiency of sulphur trioxide in the blood and tissues invite infection? Would an excess of calcareous matter in the blood account for a decrease of sulphur trioxide therein?

In my experience during the past four years, sulphur or sulphuric acid has invariably been successful in combating furunculosis and I am convinced that the blood and tissues are deficient in sulphur trioxide, else why should sulphuric acid act so promptly and efficaciously in these cases? It might be asked what checks the infection of furunculosis and prevents future attacks? Are the staphylococci killed by sulphur trioxide in the circulation, or does sulphur trioxide so alter the blood that these germs are not able to get a foothold?

It would be interesting to know in all pus conditions, not only whether the blood is deficient in sulphur trioxide, but also whether the excretion of sulphates in the urine and feces is lessened and whether this excretion rises in amount after the administration of sulphuric acid.

L. D. Bulkley, of New York, in his article, "On the Non-Surgical Treatment of Boils, Carbuncles and Felons," highly recommends an iron tonic by the name of Startin's Mixture, which gave him good results in dram doses. This mixture contains dilute sulphuric acid, ten minims to the dram, which is too small, but had he trebled the amount of dilute sulphuric acid he would have had unfailing results.

J. and R. J. Reynolds, of London, report wonderderful results during a number of years from the use of dilute sulphuric acid in a variety of pus conditions, *i.e.*, boils, carbuncles and streptococcic infections. Cases even of bronchiectasis and pulmonary tuberculosis were markedly benefited.

Having had good results in pus conditions, other than furunculosis, I should like to mention a few of them:

CASE I.—A severe and chronic case of acne rosacea yielded to treatment within a month. This patient came to see me during the stage of telangiectasis, showing diluted capillaries and many pustules, which had resisted treatment for over four years in the hands of New York and Boston specialists.

CASE II.—A chronic and severe form of acne indurata resisted the usual treatment by tonics and curettage. After a bacteriological examination, vaccines were given a trial, but without success. Dilute sulphuric acid, given in thirty-drop doses, was followed by slight improvement, and when it was increased to fifty drops the pustules cleared up.

CASE III.—Fully convinced now that sulphuric acid could be used successfully in all conditions where pus existed, I did not hesitate to give it a trial in pyorrhea alveolaris. In this case the patient had already had two teeth pulled out within the last two years. A right lower molar was very loose, very sensitive and felt about a quarter of an inch too long, so that the patient could not masticate his food. The gum was painful and much inflamed and there was a discharge of pus at the gum border. The gum over some of the other teeth likewise showed inflammation and pus could be expressed. The patient visited his dentist, who treated the condition in the usual way by scraping the roots and by painting the gums with tincture of iodine. He was informed that the tooth would probably have to be removed in the course of a few days. Talbot states that "the loosening of the teeth is their death knell, and the sooner they are removed the better." As I shall show, this statement no longer holds good, for the patient took sulphuric acid in the manner previously mentioned and when he visited his dentist four days later the tooth was firm, the inflammation had subsided, and the discharge of pus had ceased. Since then he has been taking occasional doses of sulphuric acid, for he noticed that when without treatment for a few weeks, one or the other tooth became sensitive during mastication, or that the surrounding gum was inflamed. However, he noticed with satisfaction that these symptoms disappeared within twenty-four hours after treatment.

Several other cases of pyorrhea alveolaris have been equally benefited. The teeth, however, remain very sensitive to cold liquids, owing to the retraction of the gums, and I am at present unable to say whether they will ever cover the teeth properly, as they do in a normal condition.

Judging by the medical literature and the treatment in the clinics it is surprising to me that no advantage has been taken of the announcement of the Reynolds' method for the treatment of boils and carbuncles and infections by means of sulphuric acid. There is no longer any need for such treatment as incision and suction cups (Bier's) in ordinary cases, the latter causing unnecessary suffering to an extreme degree.

Small doses are of no use, and if there is no improvement after forty-eight hours, the dose should be increased. Improvement is so rapid that it is seldom necessary to continue treatment for more than eight or ten days, usually less. The patient in most cases can himself decide when to discontinue treatment. No gastric or other symptoms were ever noticed as a result of taking this drug.

Sufferers from pyorrhea alveolaris are not to conclude that the treatment by sulphuric acid does away with the necessity of periodical visits to the dentist. On the contrary, they should be especially careful to give their teeth proper attention.

ARTERIAL HYPERTENSION: ITS RELATION TO ARTERIOSCLEROSIS AND BRIGHT'S DISEASE.

BY W. C. K. BERLIN, M.D.,
DENVER, COLO.

SYMPTOMATICALLY, arterial hypertension may be characterized by a train of symptoms entirely independent of those found in arteriosclerosis or Bright's disease. Arteriosclerosis *per se* may be characterized by symptoms and conditions entirely independent of either arterial hypertension or

Bright's disease. Bright's disease is entirely different in symptoms and conditions from those found in arteriosclerosis and arterial hypertension. These three diseases have long been classed as relating one to the other, but in the light of advanced research and knowledge the time has come when they must be separated from one another in searching for the cause of these different conditions. Heretofore the three have been believed by many to originate from the same remote cause.

Arterial hypertension is characterized by a sense of insecurity, both mentally and physically. There may be present extreme mental unrest, either exhibited as mental depression amounting to actual melancholia or mental excitability and nervousness. Mental and physical fatigue on little or no exertion are prominent symptoms. Bodily equilibrium is disturbed, and a patient may speak of staggering instead of dizziness or vertigo. There may be present a percordial distress causing great uneasiness, with a foreboding of impending dissolution. The severity of these symptoms is not always in proportion to the reading of the sphygmomanometer. I am convinced that the cause of high blood pressure is due to a toxemia or to toxemias only, but may be associated with both arteriosclerosis and Bright's disease. Most convincing of the latter assertion is the fact that arterial hypertension can and does occur without any evidence whatever of either arteriosclerosis or Bright's disease being present. The rather recent idea that arterial hypertension contributes to the safety of a kidney lesion is fallacious. One cannot but believe that the kidneys, as well as other structures, are all in equal danger from this condition.

There seem to be two forms of toxemia or intoxications responsible for arterial hypertension. Both no doubt are of intestinal origin. One in an indicanuria, the other is problematic as to origin, but may be related to the acetone bodies. Arterial hypertension due to intestinal intoxication, decomposition or fermentation resulting in an indicanuria is most amenable to treatment and is classed as the most frequent cause of high blood pressure. Thorough disintoxication measures with rigorous dietary restrictions have not failed either to greatly benefit or entirely relieve arterial hypertension in the indican class and have influenced favorably the other class or cause of hypertension, together with the internal use of the iodides, and especially when the iodine is administered intravenously. Arteriosclerosis is not well understood but is undoubtedly associated with disordered metabolism, when not following some of the specific diseases, and when occurring with arterial hypertension the toxemias or intoxications are also present and treatment would necessarily be followed along similar lines.

In a former article MEDICAL RECORD, February 14, 1914, page 292, I have taken the stand and have produced material proof that Bright's disease is purely an infectious disease, and as such has no relation to the other two diseases now under discussion. Arterial hypertension may accompany Bright's disease as a result of an intestinal fermentation or stasis, which stasis is also responsible for the infectious character of Bright's disease. In order to lend weight to the statements made above a few short case histories will be confirmative:

CASE I.—S. H. C.; age fifty-five years; short stocky man; plethoric; has always been a hearty eater and high liver. About December, 1912, became very dizzy, cyanotic and staggering; blood pressure said to be 190 mm.; came under observation May 19, 1913; blood pressure 180 mm., severe indicanuria, which was very persistent; urine perfectly free from kidney débris or albumin, thus indicating normal kidneys; arteriosclerosis absent. In this case the blood pressure was reduced in proportion to the disappearance of the indican. Under treatment of thorough disintoxication, regulation of diet and the intravenous method of administering iodine the blood pressure became normal and recovery seemed complete.

CASE II.—Miss McL.; aged nineteen years. Negative family history except for digestive disturbances. Slender and about 5 feet 4 inches tall, but fairly well nourished. This patient came under observation for a bronchitis of some years standing. Sputum was positive to a mixed variety of organisms. Tubercular bacillus negative. Infection seemed to be confined to large bronchi and upper air passages. Physical signs in chest were negative. Blood pressure 140 mm. Abdomen distended and tympanitic with tenderness over the illiocecal region. Urine contained indican, albumin (2 per cent.) casts, and other débris. Blood culture gave a pure growth of colon bacillus. Since this case had no acute symptoms it would have been classed as a beginning Bright's disease had not the infectious character been proved. The stasis in this case is more than likely responsible for a double infection, *i.e.* a colon bacillus bacteriemia with infected kidneys and a bronchitis with a mixed infection as a result of such a stasis. There were no symptoms of arteriosclerosis found in this case.

CASE III.—H. B., age twenty-seven. Negative family history. Well nourished but anemic. Red blood count, 3,500,000; white, 500,000. Blood pressure, 148. Has been troubled with intestinal disturbances for several years. Abdomen distended and tender over left hypochondrium. Evidently a severe chronic stasis attended this case. The urine was normal except for indican. Blood culture was positive to a pure growth of colon bacillus. In this case there is an absence of arteriosclerosis. There was no kidney complication but a hypertension prevailed.

CASE IV.—J. E. O., age thirty-one years. Negative family history, except father was an alcoholic. Good physical condition. City fireman for several years. Patient came under observation about one year ago for a heavy and persistent cold with some loss of weight. This attack responded to treatment with recovery. Recently this patient reappeared, complaining of extreme fatigue, shortness of breath and palpitation of the heart on the least exertion. Chest shows diminished or absence of vesicular breathing on right side. Left apparently normal. Cardiac hypertrophy with a mitral murmur was present. Abdomen distended and tender. Urine contained albumin, casts and other renal débris. Blood, sputum, and urine were positive to a streptococcus on culture. This stasis, no doubt, caused an infection of the lungs, blood and kidneys of the same type. In this case a nephritis (Bright's disease) was present, but arterial hypertension and arteriosclerosis were absent.

CASE V.—L. S., age forty-two years. Slender but very well nourished. Good family history. Has had albuminuria with casts for a number of years. This was no doubt a mild form of true Bright's disease, but treated as an infection recovery was complete. In this case there was no arteriosclerosis and the blood pressure was subnormal, *i.e.* 100 mm.

CASE VI.—L. V., age thirty years. German descent. Good physical condition. Family history positive to this condition. Car repairer, but has been unable to work for two years on account of extreme vertigo, nervousness, and insecurity on his feet. Blood pressure has been as high as 240 mm. In this case there is an absence of kidney disturbance and arteriosclerosis.

Conclusions.—(1) Arterial hypertension occurs independently of either Bright's disease or arteriosclerosis and is due to toxemia or intoxications only. (2) Bright's disease is independent of arterial hypertension or arteriosclerosis and is due to an infection only. (3) Arteriosclerosis occurs independently of either arterial hypertension or Bright's disease and may be caused by altered metabolism or toxemias.

201-202 SYMES BUILDING.

WOUND HEALING WITH THE AID OF VACCINES.

By JOHN GARDINER, M.D.,

TOLEDO, OHIO.

To allow a wound to heal from the bottom up has been proven by experience the best and quickest way. To close a wound in the presence of infection is considered bad surgery. But the following case demonstrates the advantage of combining vaccine treatment with the suturing of an infected wound, where limited portions of tissue have been lost or removed. Great tension may be employed, as in this case, with a negligible amount of cutting through of the sutures.

An infected sacral dermoid, filled with hair, was removed from a well developed patient. In an effort to get below the infected area the tissue was removed down to the sacrum, leaving a wound five inches long, two and one-half inches wide in its greatest width, and about two inches deep. The wound was closed, at least the skin flaps were approximated, and a small cigarette drain was inserted. There was immediate absorption and a general infection took place lasting four days, when it subsided. The wound was opened and an infected blood clot was removed. Staphylococcus and colon bacillus were found and a vaccine was prepared and administered.

Ten days after the operation an attempt was made to reduce the granulating surface. It was recognized that great tension was necessary, and it occurred to me to place the sutures at some distance from the wound, in order to preserve the nourishment to the parts as much as possible. Silk worm sutures were inserted, with the aid of novocain anesthesia, through the fascia, well down into the muscle, these sutures being placed three-eighths of an inch apart and alternately, one-half inch and one inch from the edges of the wound. The tension was so great, because of the natural inelasticity of the tissue in this region, there was danger that the sutures might cut through. However, there was very little pressure necrosis caused by the sutures, and no stitch abscess. The vaccine was given every five days and each inoculation was followed by a good reaction. The sutures were removed on the twelfth day. The wound was now reduced to one three inches in length, one-fourth of an inch in width and one and one-half inches in depth. The wound healed by granulation, with a scar whose greatest width was one-fourth of an inch instead of two and one-half inches as it would otherwise have been. While the granulations were being formed the tension was kept up by adhesive strips extending from one hip over the back to the opposite hip.

For the protection of the skin in applying the adhesive strips, the following method proved to be of great advantage. The general practice of pulling off adhesive plaster and applying fresh adhesive at each dressing soon takes off the epidermis and annoying ulcers of varying diameter result. This trouble can be obviated by using zinc oxide adhesive and cutting away at each dressing only that portion which covers the dressing, thus allowing the location of tension to remain undisturbed, and applying the new strips directly over these. The original adhesive strips applied in this way may remain indefinitely and will cause no trouble whatever.

Medicolegal Notes.

Improper Removal of Healthy Tissue—Evidence—Specialists—Degree of Skill and Knowledge.—In an action against a physician for the death of a patient following an operation on his nose claimed to have been caused by improper after-treatment, it appeared that the physician kept cutting away a tissue growth that formed in the nostril under the suspicion that it was a malignant growth. There was testimony tending to show that if it was not a malignant growth, but a normal product of the inflammatory process set up by the operation, its removal was not proper and might have caused the death. The court excluded a question asked an expert witness as to whether a reasonably prudent surgeon, if in doubt as to the nature of the tissue, would not have had a prompt analysis made. It was held on appeal that the exclusion of this question was error, as the plaintiff was required not only to satisfy the jury that the tissue removed was in fact healthy tissue that should not have been disturbed, but also that its removal without ascertaining its real nature, or employing the means at the physician's command to that end by causing a pathological analysis, was negligence.

The trial court was requested to instruct the jury that, as the defendant was a specialist, he was bound to have that degree of skill and knowledge ordinarily possessed by specialists, and a greater degree than that which a physician in regular practice is bound to have and exercise. The court refused to give these charges, and repeatedly told the jury that the defendant was only bound to exercise the reasonable care and skill of his profession. Once the jury was told that the defendant was not liable "if he did everything which a careful, prudent physician of his class would have done," which was immediately nullified by the additional words "or his profession."

The case conclusively showed that the defendant held himself out as a specialist in the treatment of diseases of the nose, and that as such specialist he was consulted by the deceased upon the advice of the ordinary practitioner who had attended him. Under such circumstances, the question whether the defendant was a specialist, while one of fact was primarily for his own determination, with the result that if he held himself out as a specialist it became his duty to bring to his patient's aid that degree of skill that such a practitioner assumes to possess.—Coleman v. Wilson, New Jersey Court of Errors and Appeals, 88 Atl. 1059.

Act To Authorize Sterilization of Feeble-Minded, etc., Held Invalid.—The New Jersey Board of Examiners of Feeble-Minded, created by "An act to authorize and provide for the sterilization of feeble-minded (including idiots, imbeciles, and morons) epileptics, rapists, certain criminals and other defectives" (V. L. 1911, p. 353), ordered that the operation of salpingectomy be performed upon one Alice Smith, an epileptic inmate of a state charitable institution, as the most effective operation for the prevention of procreation. On appeal the order was reversed. It was held that the statute in question was based upon a classification that bore no reasonable relation to the object of such police regulation, and hence denied to the individuals of the class so selected the equal protection of the laws guaranteed by the Fourteenth Amendment to the Constitution of the United States. The artificial regulation of the welfare of society by means of surgical operations for the prevention of procreation, being based upon the suppression of the personal liberty of individuals, must be accomplished, if at all, by a statute extending to the persons thus injuriously affected such equal protection of the laws.—Smith v. Board of Examiners, New Jersey Supreme Court, 88 Atl. 963.

Mental Healers Must Stand Examination.—In proceedings for violation of the Alabama statute, under which "all persons who treat or offer to treat diseases of human beings by any system of treatment whatsoever," must obtain a certificate of qualification from the State Board of Medical Examiners, the defendant admitted that he attempted to make cures by the power of mental suggestion, that he used harmless pills and a little dry telephone battery merely as aids to this suggestion, and did not attempt to treat cases requiring surgical operations. It was held that he must first stand an examination and obtain a certificate of qualification from the State Board, as required by Code 1907, § 1625.—Smith v. State, Alabama Court of Appeals, 63 So. 28.

New York, July 4, 1914.

POLYGLOBULIA AND DISEASE OF THE LIVER.

THE association of these two conditions has been noted for a long time. In 1907 Mosse of Berlin reported the case of a patient in whom polycythemia was associated with urobilinuria, icterus, and a splenic tumor. This case recently came to autopsy. A careful histological examination of the liver and spleen was made so that the question of the relation of polyglobulia to disease of the liver could be more thoroughly studied. Accordingly Mosse was able to present a comprehensive analysis of this subject in the *Zeitschrift für klinische Medizin*, Vol. 79, Nos. 5 and 6.

He points out in the first place that Taussig was the first to note the polyglobulia resulting from phosphorus poisoning. This observation was later confirmed by von Jaksch and Silvermann. Since then a number of observers have reported cases of polyglobulia associated with disease of the liver. One of Türk's cases was that of a 36-year-old patient with large liver and spleen and with a considerable degree of urobilinuria. There was no cyanosis of the lips, cheeks, or ears. The erythrocyte count was 10,000,000. Türk made a presumptive diagnosis of biliary cirrhosis of the liver, splenic tumor, and hyperplasia of the erythroblastic myeloid tissue. He advanced the hypothesis that the primary defect was in the erythroblastic apparatus of the bone marrow. More recently Türk included these cases with the erythremias, regarding the erythrocytosis as a secondary phenomenon. He advanced the belief that the same poison which in Banti's disease causes a chronic anemia, in other cases is set free from the diseased spleen in a smaller amount and gives rise to a hyperglobulia. In this manner Türk sought to reconcile the conception of Banti's disease with its large spleen and anemia with the conception of polycythemia megalosplenica. With this category of cases must be included those with marked cirrhotic changes in the liver, for liver and spleen share in a common functional activity just as do the spleen and bone marrow.

The clinical and pathological study of Mosse's case appears to add further weight to the above observations, namely, that in a series of cases there are sharply marked off the following phenomena: The presence during life of polycythemia, urobilinuria, icterus, and a splenic tumor; and at autopsy of a highly vascular spleen, a hyperblastic red bone marrow, and a cirrhotic condition of the liver. Mosse believes that all these cases belong to the same category, and discusses the nature of this condition. He believes that the cirrhosis of the liver, least of all, is likely to be a primary condition, in other words, that one is here dealing with the typical picture of Laennec's cirrhosis. There remain three possible interpretations: first, that advanced by Hess and Saxl, namely, an alteration in the liver cells causes a loss in the hemoglobin-destroying function of the liver; second, Türk's conception of a secondary erythrocytosis; third, the following explanation which is offered by Mosse. The anatomical cause, a primary diffuse disease of the bone marrow gives rise to an increase in the red blood cells as well as the leucocytes. This causes a secondary enlargement of the spleen. The cirrhosis of the liver is likewise a secondary manifestation. The liver is damaged as the result of an increased functional activity necessitated by the transformation of an excessive amount of noxious material. Mosse concludes that the syndrome of polycythemia with urobilinuria, icterus, and a splenic tumor is in no sense to be included among the common clinical pictures. The anatomical basis is a hyperplasia of the bone marrow, an excessive vascularity of the splenic pulp, and cirrhotic changes in the liver.

TRACHOMA IN THE MOUNTAIN SECTIONS OF VIRGINIA.

THE fact was demonstrated some time ago by Drs. I. A. Stucky and John McMullen, U. S. Public Health Service, that trachoma is unduly prevalent in certain of the mountain counties of Eastern Kentucky. After these reports had been published it was decided to make a survey of the entire Appalachian mountain chain in order to determine the extent of the spread of trachoma among a population allied by blood and affected by propinquity to the people of this infected region. The results accruing from this survey have been published in Public Health Reports June 5, by Dr. Taliaferro Clark, Surgeon U. S. Public Health Service. The survey was commenced in September, 1913, at Wheeling, W. Va., with an examination of the school children of that city for trachoma; inspections were made in 23 counties of West Virginia, during which 20,848 persons were examined, among whom 340 cases of trachoma were found, 1.63 per cent. The survey of the mountainous sections of Virginia was ended at Staunton, Va., April 29, 1914. In the course of the survey 10 counties, contiguous to the known infected territory of Kentucky and West Virginia, were visited and 7,801 persons were examined for trachoma. Of these 108 had the disease, 1.38 per cent. Clark points out that a significant fact revealed by this survey is the wide distribution of trachomatous infection throughout the greater portion of West Virginia.

The object of the survey has not been to uncover every case of trachoma, but to outline the limits of infected territory and to bring to the attention of local physicians, school boards, and other authorities the menace of the disease, and the necessity of concerted action for its eradication. The origin of the disease, so far as Virginia is concerned, is obscure, but it is Clark's belief that it has existed among the people since their earliest settlement, and that it has spread as the population increased and because of the lack of sanitary precautions.

The following recommendations with a view to stamping out trachoma in Virginia are made by Clark: (1) Systematic examination for trachoma should be made of all school children of the State; (2) all children suffering from active trachoma should be excluded from school under medical supervision until pronounced in condition to return without danger to others; (3) the expense of such medical supervision of school children should be borne by the State whenever necessary; (4) a school nurse should be employed wherever practicable, whose duty would be to visit the homes of children debarred from school by reason of trachoma and put into practice, under the physician's direction, the principles of control of the disease from the standpoint of the individual and the public; (5) a campaign of education in infected territory by means of talks to school children and the distribution of printed information relative to the dangers and prophylaxis of trachoma; (6) free hospitals to be erected at suitable and convenient points; (7) the co-operation of the mining companies should be secured in order that a systematic examination of all miners may be made by their physicians, and all cases of trachoma found among them treated; (8) a systematic effort should be made to improve the sanitary condition of rural schools to the end that the dangers of school infection may be lessened.

ETIOLOGY OF THE INFECTIOUS DISEASES.

WITHIN the past few years our knowledge of the etiology of the infectious diseases has greatly increased. In an address delivered before the Richmond Academy of Medicine and Surgery on February 10, 1914, and published in Public Health Reports, April 3, 1914, Dr. John Anderson, Director of the Hygienic Laboratory, dwelt on the recent additions to our knowledge of the etiology of the infectious diseases. He pointed out that while very recent years have witnessed remarkable advances in our knowledge of many of the phenomena of disease, in our understanding of its true nature, there was a period not long ago in which little was done to forward our knowledge of some important infectious diseases endemic almost throughout the civilized world, and research workers realized that new methods or agencies must be employed. It has been due to the recognition and application of certain methods and agencies of research that our present understanding has been obtained.

Furthermore, pari passu with the advance of knowledge in this direction has come the discovery that some diseases formerly thought not to be communicable really belong to the infectious class. Poliomyelitis is the most outstanding example. The use of the monkey as an experimental animal, according to Anderson, has contributed more than any other single factor to the important recent additions to our knowledge of the acute infections. Another important advance, to which attention was drawn by the speaker, was in the adoption of methods of experiment by which the infective material was introduced into the body so that it was brought into immediate contact with the organs or tissues primarily and most seriously affected in the natural disease, as in experimental meningitis and poliomyelitis, where the infective material is put directly into the cranial or spinal cavity.

The progress of knowledge regarding the infectious diseases in a comparatively short space of time has been wonderful, and has paved the way to the prevention and treatment of these maladies. In the field of medical research, American investigators have played a prominent part, and probably no living student of medical research has done more to clear up obscure points in the origin of disease than Theobald Smith.

A NEW REACTION IN THE CEREBROSPINAL FLUID.

IF one cubic centimeter of cerebrospinal fluid is placed in a small test glass, and an equal amount of a 1-1,000 potassium permanganate solution is superadded while the glass is held at an angle, a negative behavior shows that the fluid is normal, the glass having previously been shifted to the perpendicular. If the fluid is not normal a yellow color zone will appear at the junction of the two liquids, and if the glass is now shaken the entire bulk of the fluid becomes bright yellow, the rose-violet color of the permanganate solution vanishing. But if the fluid is normal shaking causes it to assume the rose-violet hue of the reagent. The more decided the reaction in a pathological fluid, the more promptly it appears. Thus far nothing is known of the rationale or significance of a positive reaction.

We are indebted for this innovation to Piero Boveri, who is connected with the neuropathological division of the Ospedale Maggiore of Milan. He has submitted 40 patients with nervous affections to the test and has established a scale between the highly positive and negative extremes, in which promptness, the length of the cycle, and other elements figure. The outcome of this series of examinations has convinced the author that a positive result is the most delicate evidence that something pathological is present in the cerebrospinal fluid. For one thing the albumin content is increased, not in a mere majority, but in all cases. There is no parallelism with any kind of cell count. The most marked reactions are seen in myelitis. It is possible that escape of hemoglobin into the fluid will turn out to be the cause of the reaction. Another hypothesis, quite in line with the work

of others, is that the latter is provoked because of the presence in the fluid of the catabolic products of endogenous albumin.

The Possible Relationship of Endemic Goiter to Water Supply.

In January, 1913, Major Robert McCarrison, of the Indian Medical Service, delivered the Milroy Lectures before the Royal College of Physicians of London, taking as his subject the etiology of endemic goiter. These lectures created somewhat of a sensation in the medical world. McCarrison concluded from a study of the behavior of endemics and of authenticated outbreaks occurring in his own experience and in the experience of others, that endemic goiter is due to the existence of a specific living excitant. He claimed that living organisms bringing about goiter were found in water and that these organisms and not dissolved salts were the cause of the affection. Drs. Taliaferro, Clark and Claude C. Pierce, Surgeons U. S. Public Health Service, in Public Health Reports, April 17, 1914, analyze McCarrison's findings and summarize their own conclusions as follows: (1) The cause of endemic goiter is not yet determined. (2) The extensive prevalence of goiter in rural communities, where families are widely separated and have separate water supplies, tends to preclude the possibility of the affection being due to a water-borne, living, organic excitant. (3) The enormously greater prevalence of goitrous endemicity in regions underlaid by carboniferous, devonian, and silurian strata, can certainly bear some relation to the water supplies which should carry in solution, or do not, as the case may be, the same or similar chemical substances. (4) The observations of Howell on the prevalence of endemic goiter in an arid region of New South Wales, in which the sole water supply is rain gathered and stored in cisterns, point to the probability of the affection being due to a deficiency of certain necessary chemical substances. (5) The experiments of Marine and Lenhart, by which goitrous fish were cured by the addition of iodine in the form of Lugol's solution to their water supply, indicate that the affection may be due to a lack of iodine in the drinking water or in vegetables grown on the soil of goitrous districts. In fact, the administration of iodine, either locally or internally, is a recognized method of treatment of the affection in man. Many recoveries are reported as due to this treatment. (6) The experimental production of goiter in man by McCarrison is in need of corroboration. His interpretations also are somewhat indefinite.

Needless Alarm.

At the meeting of the American Institute of Homeopathy held in Atlantic City this week, Dr. DeWitt Wilcox of Boston, in his presidential address, as reported in *The Sun*, warned his hearers that "the American Medical Association has formed an unholy alliance with the medical departments of the army and navy by which they propose to own and control every medical college in the country, together with all the university hospitals, thus getting into their own grasp all the examining and licensing boards of the United States." The lingering vibrations of the American Medical Association meeting of the previous week must have affected Dr. Wilcox unpleasantly, for the facts do not warrant his fears. Our homeopathic brethren are well represented on all the State examining boards and there has been no attempt to prevent the licensing of graduates of homeopathic colleges. If any of the colleges of that school are below standard they must bestir themselves and rise to the grade required of all, regular, homeopathic, and eclectic alike. As for the American Medical Association getting control of the State boards, it would have to reckon not only with the homeopathic and eclectic members of those boards but with the members of the State legislatures as well. Dr. Wilcox's alarm is purely "psychological."

The Early Period of Microscopy.

It would be a truism to say that no one factor has contributed more to the advance of medical knowledge than the microscope. Without the microscope medical research would be impossible. At a meeting of the Section of the History of Medicine of the Royal Society of Medicine, held in London on May 27, 1914, Dr. Charles Singer gave an account of the earliest period of microscopy. It seems that convex lenses, though known for centuries, were first adopted for the purpose of investigation at the end of the sixteenth century. They were probably used by Mouffet and Hoefnagel more than 60 years before such workers as Hook and Leeuwenhoeck perfected their methods of manufacture. The compound microscopic was discovered more or less accidentally by Zacharias, a Dutch spectacle maker, about 1590. The introduction of the microscope into medicine may be especially attributed to Borel and Kircher. The pioneer period of microscopic discovery closed and the classical period commenced with the work of Hook and Malpighi after the middle of the seventeenth century.

News of the Week.

Plague in the South.—Announcement of the discovery of a case of bubonic plague in New Orleans was made by the health officers of that city on June 27. The patient had been in the city for eleven days, but it could not be learned where he had contracted the disease.

Studying Pellagra.—The commission for the study of pellagra, composed of physicians from the Medical Corps of the United States Navy and Army, the Public Health Service, and the New York Post-Graduate Medical School, was joined on June 20 by Dr. Simon Flexner and Dr. Peyton Rous of the Rockefeller Institute, New York, and Dr. Linsly R. Williams, deputy commissioner of health of New York State. The members of the commission are now at Spartanburg, S. C. It has been estimated that between 50,000 and 75,000 cases of pellagra exist in the South, while of the 8,000 cases studied by the commission 28 per cent. have proved fatal.

Seaside Hospital Opens.—The Seaside Hospital of St. John's Guild, situated at New Dorp, Staten Island, was opened for the summer on June 21.

Sanatorium Dedicated.—In the presence of a number of officials and guests of the Metropolitan Life Insurance Company, on June 20, the tuberculosis sanatorium erected by the company for the benefit of its employees was formally dedicated and opened. The sanatorium is situated on

Mount McGregor, nine miles from Saratoga, N. Y., and at present houses sixty-nine patients. When it is completed accommodations for 229 will be provided. The Metropolitan is the first insurance to establish such provisions for the treatment of its employees, and its right to do so was passed upon by the Supreme Court of the State before the work was undertaken.

Medical Museum.—The Wellcome Historical Medical Museum which was founded in London by Mr. H. S. Wellcome in connection with the Seventeenth International Congress of Medicine, was reopened on May 28 last as a permanent institution. Since its closing last October the museum has received a number of additions and the collections have been rearranged. The exhibition is open daily at 54A Wigmore street, Cavendish Square, W., and is free to members of the medical profession on presentation of their visiting cards, and cards of admission can be obtained by others interested on application to the curator, with this important exception: "Ladies will be admitted, *only* if accompanied by a qualified medical man." Thus are the activities of the strenuous suffragette feared even in scientific circles.

Public Health Sunday.—Forty of the Philadelphia churches opened their pulpits to physicians on June 21 in celebration of "Public Health Sunday."

New York State Board of Medical Examiners.—Dr. Hans Zinsser, professor of bacteriology in Columbia University, New York City, has been appointed examiner in bacteriology in place of Dr. H. U. Williams of Buffalo, who resigned.

The Board of Regents has revoked the medical license of Abraham Glickstein on the complaint of the Medical Society of the County of New York.

New Rockefeller Gift.—The trustees of the Rockefeller Institute for Medical Research, New York, have recently received from Mr. John D. Rockefeller an additional gift of $2,550,000, which is to be used for the acquirement of land adjoining the present holdings of the Institute on the East River and the erection and equipment of new laboratory buildings. Only a short time ago Mr. Rockefeller gave $1,000,000 to the Institute for the establishment of a department for the study of diseases of animals, making his total gifts to the Institute thus far, exclusive of the land which it now owns, amount to about $12,500,000. This means that the Rockefeller Institute is the most richly endowed institution for medical research in the world.

Sterilization Law Killed.—The United States District Judge of the Southern District of Iowa on June 24 declared unconstitutional, and therefore null and void, the law passed by the last General Assembly of Iowa providing for the sterilization of certain criminals. This decision was based on the belief that the penalty was in violation of the Constitution, which provides that cruel and unusual punishment shall not be inflicted.

American Medical Association.—The following officers were elected at the annual meeting at Atlantic City, June 23-26, 1914: *President*, William L. Rodman, Philadelphia; *1st Vice-President*, E. S. Fairchild, Kansas City, Mo.; *2d Vice-President*, D. Misner R. Townsend, New York; *3d Vice-President*, Alice Hamilton, Chicago; *4th Vice-President*, William E. Darnall, Atlantic City, N. J.; *Secretary*, Alexander R. Craig, Chicago; *Treasurer*, William Allan Pusey, Chicago; *Trustees*, Philip Marvel, Atlantic City; W. T. Sarles, Sparta, Wis.; Philip Mills Jones, San Francisco. The next meeting of the association will be in San Francisco in June, 1915.

Medical Licenses Granted.—As a result of the spring examinations eighty-one physicians have received licenses to practice medicine in the State of North Carolina. There were 118 applicants in all.

The Louisiana State Board of Medical Examiners has licensed fifty-nine physicians to practice in that State, refusing five others who had applied.

The Mississippi State Board of Health examined fifty-five applicants on June 16, 17, and 18, and granted licenses to thirty-five.

Cripples' Welfare Commission.—This national commission held its annual meeting in Philadelphia on June 20, following the convention of the American Orthopedic Association. Plans were made for the establishment of a central bureau for literature relating to the education and care of cripples, and the *American Journal of Care for Cripples*, published by the Federation of Associations for Cripples, in New York, was designated as the official organ of the commission. The following officers were elected: *President*, Dr. Arthur J. Gillette, St. Paul, Min.; *Vice-President*, Dr. H. Winnett Orr, Lincoln, Neb.; *Secretary*, Mrs. E. R. Solenberger, Lansdowne, Penn.; *Treasurer*, Dr. John L. Porter, Chicago; *Editor*, Mr. Douglas C. McMurtrie, New York. The other members of the commission are Dr. Leonard W. Ely, San Francisco; Dr. A. H. Freiberg, Cincinnati, O.; Dr. Michael Hoke, Atlanta, Ga.; Dr. Robert W. Lovett, Boston, Mass.; Dr. John Ridlon, Chicago; Dr. Harry N. Sherman, San Francisco; Dr. David Silver, Pittsburgh; Hon. George W. Sweney, Marion, O., and Dr. H. Augustus Wilson, Philadelphia.

Nurses' Home Begun.—The cornerstone of the new home for nurses of the German Hospital, Williamsburg, was laid on June 21, by ex-Mayor Kline in the presence of five thousand persons. The home will cost $45,000 and will be ready for occupancy in October.

Cocaine Users Sentenced.—Five persons, four men and one woman, convicted of using cocaine, were sentenced in the Court of Special Sessions last week to terms of from six months to one year in the penitentiary for using cocaine. In the Court of General Sessions a man, convicted of selling cocaine, received a sentence of six years and one month.

Home of Surgery.—At the annual meeting of the American College of Surgeons in Philadelphia on June 22, a movement was begun for the establishment of a permanent home of surgery in Washington, for which an endowment fund of half a million dollars will be needed. More than $100,000 was pledged by the members of the association within an hour, and it was predicted that the fund would easily reach $1,000,000. The college now has a membership of 3,200, having admitted 1,100 surgeons to fellowship at this meeting. Dr. Thomas Addis Emmett of New York was elected an honorary fellow of the college.

New Post-Graduate School.—With the purpose of increasing the efficiency of the physicians and surgeons of the South, a number of physicians of Louisiana have recently formed and incorporated the New Orleans Post-Graduate School of Medicine. Dr. Homer Dupuy, chief of the eye, ear, nose, and throat department of the Charity Hospital, New

Orleans, has been made president of the school, which includes among its other officers and board of directors a number of the most prominent medical men of the city.

Sick Rate at Vera Cruz.—The sick rate among the soldiers and marines at Vera Cruz decreased slightly during the week ending June 20 as compared with the previous week. In the army the rate fell from 2.15 to 2.03, and among the marines from 2.88 to 2.30. Forty-three soldiers and marines are being cared for in the hospital and seventeen are reported ill in quarters.

Dr. Morton Reinstated.—Dr. William J. Morton, who was debarred from the practice of medicine in New York State by his conviction some time ago in the Federal Courts of illegal acts in relation to a mining promotion, was reinstated by the State Board of Regents at its regular meeting on June 25. This action was taken under the authorization of a special act of the Legislature passed at the last session, and was based particularly upon a letter from the President of the United States, a letter from the judge who presided at Dr. Morton's trial, a letter from the prosecuting attorney, and the favoring attitude of medical societies and many prominent physicians.

City Death Rate.—The death rate of New York City for the week ending June 20 was only 11.42 per 1,000 of population, the lowest rate on record for any week since 1868 when the Department of Health began the compilation of statistics. The total number of deaths was 1,222. Pulmonary tuberculosis and pneumonia were the only causes of death showing increases as compared with the corresponding week of last year, while all the age groups showed decreases, with the greatest decline in that below five years of age. The death rate has dropped below 12 per 1,000 only three times in the history of the department. For the first twenty-five weeks of this year the death rate was 14.91, as compared with the 15.18 for the same period of 1913.

Gifts to Charities.—A large number of charitable institutions receive bequests under the will of the late Mrs. Morris K. Jesup, of New York, among them being the Presbyterian Hospital, New York, $150,000; the Manhattan Eye and Ear Hospital, New York, $50,000; the Woman's Hospital, New York, $150,000; the General Memorial Hospital, New York, $10,000; St. Luke's Hospital, New York, $10,000, and the Home for Consumptives, Denver, Col., $50,000.

The New York Eye and Ear Infirmary receives a bequest of $10,000 under the will of the late Miss Serena Rhinelander of this city.

Personals.—Dr. Godfrey Roger Pisek of New York received the honorary degree of doctor of science from the University of Vermont at its 110th commencement on June 24.

Dr. Henri de Rothschild of Paris, who prefers to use his medical title only although he is a baron of the Austrian Empire, was shot on June 21 by a milk dealer of Paris who says that his business was ruined by the opening of one of Dr. de Rothschild's philanthropic milk stations in his neighborhood. Dr. de Rothschild was not seriously wounded.

Dr. Josephine Walter of New York was recently appointed consulting physician to the Medical Department of the New York Infirmary for Women and Children and was also appointed a trustee of the Infirmary. The latter appointment gives great satisfaction to the women connected with the hospital and to the women of the profession generally, as it has long been felt that the Board of Trustees of the infirmary would be benefitted by a larger representation of physicians. Dr. Walter has served as attending physician at the infirmary for a number of years, and as an appreciation of her faithful services and a token of the high esteem in which she is held by her associates in the hospital, she has been presented by them with a beautiful silver loving cup.

Dr. Margaret N. Sullivan, president of the Child Welfare Association of New Jersey, has been appointed assistant to the chief surgeon, Dr. J. J. Mooney, at the Jersey City Hospital. Dr. Sullivan is the first woman physician to serve upon the hospital staff.

Mr. James U. Norris, assistant superintendent of the Rockefeller Institute, has been appointed superintendent of the New York Polyclinic Medical School and Hospital, succeeding Mr. John Gunn, resigned.

Medical Society Elections.—Medical Society of North Carolina.—Annual meeting at Raleigh on June 16 to 18. Officers elected: *President*, Dr. Lewis B. McBrayer, Asheville; *Vice-Presidents*, Dr. J. J. Philips, Tarboro; Dr. Charles W. Moseley, Greensboro, and Dr. Samuel M. Crowell, Charlotte; *Secretary*, Dr. John A. Ferrell, Washington, D. C.

Litchfield County (Conn.) Medical Society.—Annual meeting at Winsted on June 12. Officers elected: *President*, Dr. Elias Pratt, Torrington; *Vice-President*, Dr. Robert Hazen, Thomaston; *Secretary*, Dr. Charles H. Turkington, Litchfield.

Complimentary Dinner to Dr. Edred Corner.—On the evening of June 26 at the Waldorf-Astoria Hotel, New York, Dr. W. Seaman Bainbridge gave a complimentary dinner to Mr. Edred Corner, F.R.C.S., surgeon to St. Thomas's Hospital, London, and to other British and American medical friends. Mr. Corner gave an address on the surgery of the knee joint; Dr. W. E. Nicholls Dunn, the medical officer in charge of the hospital at Luxor, Egypt, gave an interesting account of the diseases met with in Egypt, and Dr. Eugene Fuller of New York gave a description of his operation for the relief of gonorrheal rheumatism.

Obituary Notes.—Dr. Daniel William Flemming of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1889, died at his home on June 14, aged 54 years.

Dr. George Frederick Reinhardt of Berkeley, Cal., a graduate of the University of California, Medical Department, in 1900, professor of hygiene in his alma mater since 1903, for several years president of the State Board of Medical Examiners, and a member of the American Medical Association, the Medical Society of the State of California, and the Alameda County Medical Society, died at the University of California Infirmary, of which he was physician in charge, on June 7, after a short illness, aged 45 years.

Dr. Samuel H. Moore of Indianapolis, Ind., a graduate of the Indiana Medical College, Indianapolis, in 1870, a veteran of the Civil War, died at his home, from paralysis, after a long illness, on June 15, aged 71 years.

Dr. Charles M. Butterworth of South Bend, Ind., a graduate of the Medical College of Ohio, Cincinnati, in 1889, first city health officer of South

Bend, formerly county physician and a member of the staff of the Epworth Hospital, and a member of the American Medical Association, the Indiana State Medical Association, and the St. Joseph County Medical Society, died at his home, from pneumonia, after a short illness, on June 12, aged 47 years.

Dr. HERBERT SNOWDEN FAIRALL of Deep River, Minn., a graduate of the State University of Iowa, College of Medicine, Iowa City, in 1903, died at his home, from pneumonia, after a brief illness, on June 9, aged 35 years.

Dr. WILLIAM HENRY POMEROY of Springfield, Mass., a graduate of the Harvard University Medical School in 1886, visiting physician to the Springfield Hospital since 1898, to the Home for the Friendless since 1899, and to the Children's Home since 1889, for many years post surgeon at the United States Army Barracks in Springfield, and a member of the American Medical Association and the Massachusetts and Hampden District Medical Societies, died at his home, from heart disease, suddenly on June 10, aged fifty-six years.

Dr. EDGAR H. NEYMAN of Milwaukee, Wis., a graduate of University of Kiel, Germany, in 1890, died at his home from pneumonia, on June 7, aged forty-nine years.

Dr. FREDERICK FERDINAND RUDOLPH BERLIN of New York, a graduate of the University and Bellevue Hospital Medical College, New York, in 1900, and a member of the American Medical Association, the New York State and County Medical Societies, and the Medical Society of Greater New York, died at his home suddenly on June 14, aged fifty-five years.

Dr. SIMON MARX of New York, a graduate of the College of Physicians and Surgeons, New York, in 1884, surgeon to the New York Maternity Hospital, gynecologist to the Red Cross Hospital, formerly lecturer on obstetrics at the New York Post-Graduate Medical School, and a member of the New York Academy of Medicine, the New York State and County Medical Societies, and the New York Obstetrical Society, died at his home on June 16, aged fifty years.

Dr. MARVIN REED PALMER, chief surgeon of the Police Department of New York, and for twenty-five years connected with the service, died on June 20, following an operation for appendicitis a few days before. Dr. Palmer was fifty years of age and was graduated from the College of Physicians and Surgeons, New York, in 1882.

Dr. RUPERT NORTON of Baltimore, assistant superintendent of the Johns Hopkins Hospital, a graduate of the Harvard University Medical School in 1893, and a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, and the Baltimore City Medical Society, died at the hospital, from typhoid fever, on June 19, aged forty-seven years.

Dr. EDWARD M. SHIPP, Surgeon, Lieutenant Commander, U. S. N., in command of the Puget Sound Naval Hospital, a graduate of the Medical College of Virginia, Richmond, in 1891, and a member of the American Medical Association, died at the Naval Hospital, Puget Sound Navy Yard, Wash., on June 17, aged forty-six years. Dr. Shipp saw active service in the navy during the Spanish war, and had served also at the Naval Hospital, New York, and Naval Medical School, Washington, and as commander of the Naval Hospital at Yokohama.

Dr. THOMAS G. FOX of Hummelstown, Pa., who for some years had had the distinction of being the oldest living graduate of the Jefferson Medical College, Philadelphia, from which institution he received his degree in 1851, died at his home on June 18, aged eighty-seven years.

Dr. JOHN SENTER DAVIS of Lone Oak, Ky., a graduate of Vanderbilt University, Medical Department, Nashville, Tenn., in 1892, and a member of the Kentucky State Medical Association, the Southwestern Medical Society, and the McCracken County Medical Society, died suddenly, after a brief illness, in a sanatorium at Memphis, Tenn., on June 15, aged 46 years.

Dr. DANIEL LANGAN of Clinton, Ia., a graduate of the State University of Iowa College of Medicine, Iowa City, in 1863, a veteran of the Civil War, and a former president of the Clinton County Medical Society, died at his home on June 13, after several weeks' illness, from nephritis, aged 79 years.

Dr. JAMES H. MORGAN of Wilmington, Del., a graduate of the Jefferson Medical College, Philadelphia, in 1889, died suddenly at his home, from apoplexy, on June 17, aged 56 years.

Dr. CALEB SCATTERGOOD MIDDLETON of Philadelphia, a graduate of the Homeopathic Medical College of Pennsylvania, Philadelphia, in 1862, died at his home at Ardmore, on June 24, aged 75 years.

Dr. FREDERICK JOHNSON KINNEY of Olds, Ia., a graduate of the Northwestern University Medical School, Chicago, in 1912, died at his home after a brief illness, on June 12, aged 27 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HOSPITAL SUNDAY—DEGRADING SCENE IN ST. PAUL'S CATHEDRAL — OLIVER-SHARPEY LECTURES — OUTBREAK OF DISEASE IN SHEEP—TRAINING OF MIDWIVES—HOSPITAL SHIP STRANDED.

LONDON, June 19, 1914

THE week opened with Hospital Sunday and collections were made at the places of worship of all denominations. At St. Paul's Cathedral the annual Hospital Sunday service was attended, as usual, by His Majesty's judges, accompanied by the lord mayor, sheriffs, aldermen, and councillors. The female suffrage fanatics seized this occasion to make a more disgraceful demonstration than would be thought possible for their most degraded followers. As soon as the anthem began one of them shouted and police who had been stationed in aisles went to remove her. She had been chained to the plank connecting a row of chairs and either the whole row must be removed or the plank sawn through. The latter plan was adopted, a saw obtained, and while the organ and choir continued the anthem the plank was sawn in halves and the woman, chair, and chain affixed to her taken out. Meanwhile there was great disturbance. Two women flung themselves on the floor and shrieked and kicked. One chanted "God Save Emmeline Pankhurst." People stood up in their places and the interrupters kept up deafening noises. Some were gagged by those near—hands and handkerchiefs being freely applied. The indignation of the public generally was deep before this exhibition. On Sunday, too, at Hampstead Heath the suffragettes held or tried to hold a meeting. A crowd

surrounded them and endeavored to carry the platform to the pond. The police got the woman speaker off before reaching it but the platform was broken and thrown into the water, in which also some of the suffragists got ducked. In Hyde Park also an attempt to hold a meeting was prevented by the crown. A heavy thunderstorm dispersed the would-be speakers. Other meetings in the previous week had roused the mob in different places. Yet the government, which pretends not to fear the civil war threatened by its action and policy, drifts helplessly along unable to control a few female fanatics.

The Oliver-Sharpey lectures of the Royal College of Physicians were this year delivered by Dr. Gowland Hopkins who devoted them to an exposition of some of the effects which follow upon "changes in the reaction of the blood." The lecturer is Reader in Chemical Physiology at the University of Cambridge and you will therefore be prepared to hear that the subject was treated from the most advanced standpoint of these sciences. Valuable essays you may term them bringing certain questions up to date, but as rather abstruse reports more adapted for reading than for listening. Indeed one might be excused for wondering how many of the eminent physicians present could grasp their significance on simply hearing them.

It is a common observation that the blood is alkaline and that giving alkaline medicines tends to increase that reaction while acids decrease it, just as it is also said that the development of acids in the blood or in the tissues constitutes the state called acidity. But this rough physico-chemical explanation is unsatisfactory and may be met at once with the statement that whatever the reaction the blood is in fact neutral or nearly so and is maintained in that condition by the action and reaction of factors which confine its variations within extremely narrow limits. Dr. Hopkins put the effects of alkalies as increasing and acids decreasing the oxidative processes of metabolism. Evidence as to the effect of acidity he held was shown by Rona and Willenks's experiments on the isolated perfused heart, which prove that the utilization of sugar by the heart is depressed by rise of acidity in the circulating medium. But reactions in the blood must affect the tissues also and changes may take place in these, of a temporary character in health, or more permanent under abnormal conditions.

In 1907 the lecturer jointly with W. M. Fletcher investigated the conditions of lactic acid in muscle. They showed that the estimation of the amount in resting muscle had been greatly exaggerated as no small proportion of this had been produced by the manipulations of the analyst and further that a sufficient supply of oxygen to the muscle caused a disappearance of the lactic acid *in situ*. They suggested that this removal does not necessarily imply actual oxidation of the acid, but rather the restoration of some complex from which it arises, a reversal of a reaction under oxygen. But the lecturer suggested that a very low concentration of lactic acid in other organs as well as muscle might be normal even when the cell or fibre was resting, though increase was always imminent. With regard to muscle in particular he quotes Mines as formulating as a possibility that every localized production of lactic acid in the fiber at high concentration might be the cause of muscular contraction and he seemed to intimate agreement with this view as he spoke of it as perhaps having been vaguely in the minds of many.

Scrapie is the name given to a disease which lately appeared among the sheep in the northern counties and along the Scottish border. It is not, however, a modern development, but was known in these islands as well as on the continent two centuries ago. Dr. J. P. McGowan has investigated it in the Laboratory of the Edinburgh College of Physicians and his report will be very gratifying to farmers for he does not consider it contagious—a conclusion borne out by the farmers' experience as some of them have got rid of it by bringing on to their farms healthy young sheep to mix with their flocks. Dr. McGowan found the *Sarcocystis tenella* a prevailing parasite, but the symptoms of scrapie only appeared when it was present in large numbers. Rabbits developed symptoms of scrapie when inoculated from the muscles of affected sheep, but not from healthy ones. The first symptom seems to be itching, for the animals show every evidence of skin irritation which goes on to emaciation and weakness—the parasite increasing to great numbers in the muscles. The report advises to continue the plan of mixing fresh members with the flock, but never of breeding from those affected.

The annual meeting of the council for promoting the higher training of midwives was held on Wednesday when Lady Balfour spoke of amalgamation with another branch of their work and Dr. Eric Pritchard gave statistics showing that whereas fourteen years ago their infant mortality was 1 in 7 it was now only 1 in 10. This he claimed was in great measure due to the excellence of the training of midwives and the influence of those trained.

Telegrams announce that yesterday the hospital ship *Maine* had gone ashore on a small island on the southeast coast of Mull in the Firth of Lorne. All the *Maine's* boats had been lowered and a number of the patients landed and accommodated under canvas. The scene of the stranding is a wild rocky coast fully exposed to the swell of the Atlantic. But several vessels are reported to arrive to succor the *Maine* and it is expected the invalids and crew will all be brought away safely.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

HEALTH WORK AMONG NAVVIES—VACCINOTHERAPY IN PUERPERAL INFECTION—MALARIA DURING THE PUERPERIUM—RASHES FROM MANGOES—IMPROVED HEALTH CONDITIONS IN MANILA—MEASLES ON A UNITED STATES TRANSPORT.

MANILA, P. I., May 12, 1914.

EXPERIENCE in the Philippines has shown that where large numbers of workmen are collected for the purpose of carrying out extensive public works, such as the building of railroads, the grading of wagon roads, the laying of sewers, etc., unless the rules of primary sanitation are carefully observed a high mortality and morbidity rate results in almost every instance. The principal trouble is usually due to intestinal diseases, the transmission of which is caused by the faulty disposition of human excrement. Malarial fever is also an important factor in camp life. On the new wagon road which is being built from Baguio, which is at an elevation of 5,000 feet, to Bauan, on the sea, a distance of 56 kilometers, 1600 to 2000 men have been continuously employed during the past four months. This labor was largely recruited among the Igorot and Ifugao wild tribes. The former are known frequently to be afflicted with or to have

among them carriers of bacillary dysentery. Only one death has taken place and there have been but a few cases of illness. An inspection made recently of the camps shows that while in many respects there is much room for improvement, the disposal of human excrement has been carried on in a sanitary manner and it is to this that the good results are probably due. A railroad is also being constructed between the same points and similar success has been had with the workmen who are employed on that project. That the danger of the spread of disease is ever present was well shown by the fact that a high morbidity rate was continuously present among a group of Italian laborers who were employed on tunnel work and who refused to carry out the sanitary measures which had been prescribed for them.

The regular monthly meeting of the Manila Medical Society took place in the amphitheatre of the College of Medicine and Surgery at 8:30 P. M., May 4, 1914. The first paper was read by Doctor Fernando Calderon, Professor of Obstetrics in the University of the Philippines, and was entitled "Vaccinotherapy in Puerperal Infectious Fevers." The author came to the conclusion, after two years' experience in the Philippine General Hospital, that vaccinotherapy had little or no influence upon cases which had been treated there. The second paper, entitled "Malaria During the Puerperium," was read by Doctor M. Tolentino. The author stated that the administration of quinine for malaria during the puerperal period apparently had no untoward effects and did not interfere with the pregnancy.

A preliminary report on the "Lymphagogic Action of the Mango" was read by Doctor R. B. Gibson. The author stated that preliminary investigations made on the dog indicated that the mango had no lymphagogic action. In view of the frequent rashes which are produced in persons presumably by mangoes, he requested that cases be referred to him in order that the matter might be given further study.

During the month of April the death rate for the city of Manila reached a lower point than for any other April since American occupation. The rate was 21.16 per 1000. This is most interesting when it is remembered that nearby foreign ports with which the Philippines are in intimate communication are having epidemics of plague, smallpox and typhus fever. It also affords striking proof of what modern health organization may be able to accomplish in the control of dangerous communicable diseases. The danger from an increased death rate in Manila due to an increase among the intestinal diseases was happily averted by the appearance of rains, which made it unnecessary to use water for any length of time from the polluted Mariquina River.

The last transport which arrived from the United States had a number of cases of measles aboard. In view of the modern conceptions with regard to the transmission of this disease, only those persons were placed in quarantine who could not give satisfactory evidence of having had a previous attack. Measles in the Philippines is ordinarily a very mild disease and it is only apparently when a new strain is introduced from the United States or Europe that it assumes a severe type which is capable of causing death. For this reason the local health authorities regard measles as one of the major quarantinable diseases.

DANGER OF OXYTOCICS IN OBSTRUCTED LABOR.

To the Editor of the Medical Record:

Sir:—In the issue of your journal of May 30 there appears an article by Dr. S. J. Druskin of New York upon "Cesarean Section," which contains some statements which I feel should not go unchallenged. The article, taken as a whole, is an excellent one and I heartily agree with most of the statements made and deem it quite unfortunate that the author should have spoiled it by making certain recommendations.

The point upon which I would take issue with him is that of the administration of such a powerful oxytocic as pituitrin in cases where there is even a suspicion of mechanical obstruction to delivery. In his Case No. II he gives his measurements which he clearly understood to indicate a contracted pelvis. He states: The patient was admitted to hospital January 11, at 6:30 A.M., after having been in labor for six hours, and she was allowed to continue in labor until January 13 at 11 A.M., nearly 60 hours after labor had set in. Examination revealed an occipitoposterior position, a condition itself which should absolutely forbid the administration of pituitrin; still with this fact and the fact of a generally contracted pelvis before him the doctor gave this most powerful of all ecbolics.

Again, in summing up his recommendations for the management of cases of contracted pelvis he says: "Having given the natural forces a trial, having strengthened the labor pains by the administration of pituitary extract . . . and having failed to deliver the child by the natural route, we still have at our command an operation that is relatively safe and efficient, namely, the extraperitoneal cesarean section."

Now, I must protest against the recommendation to use so powerful an ecbolic where there is any obstruction to delivery, no matter whether it be due to a contracted pelvis or some malposition. Such teaching is dangerous in the extreme and should not go unchallenged.

While we all recognize in this preparation a valuable adjunct in obstetric practice we must also recognize its dangers and limitations. The administration of pituitary extract in cases of contracted pelvis is like sending an irresistible force against an immovable object—something must happen; and in this case I would certainly expect this to be a ruptured uterus with death of the patient as a consequence.

6. A Study of Extra-Pulmonary and Other Sounds Which May Lead to Errors in the Diagnosis of Pulmonary Tuberculosis. J. B. Hawes.
7. A Plea for Early Operation for Gallstones Based on Autopsy Records. J. C. Hubbard.

2. Interrelation of Graves' Disease and Tabes.—H. Barkan states that Pierre Marie in 1892 was the first

to call attention to the simultaneous appearance and possible interdependence of the symptoms of Graves' disease with those of incipient or already well developed tabes. Judged by the history and physical findings in eight cases, the author believes that Marie's opinion was correct and that the coincidence of these diseases and a possible relationship when they are so coincident has been somewhat neglected in medical literature and teaching. All of the patients were afflicted at the same time with Graves' disease and tabes. All but one showed a positive Wassermann reaction; all showed the cardinal symptoms of tabes; the Argyll-Robertson pupil and the absence of the patellar or tendo Achilles reflex; all but two showed Romberg's sign; three cases in addition to the cardinal symptoms showed primary optic atrophy; one case showed marked ataxia, two cases showed distinct areas of paresthesia, and one case showed lancinating pains. Six of the eight patients admitted having had lues. As a group they presented just as typical a picture of Graves' disease. All showed exophthalmus, a pulse varying from 96-120, a fine tremor of the extended hands and tongue, and a palpable and enlarged thyroid, though to a slight degree in all but one; all complained of perspiration, of restlessness, and nervousness. All showed marked loss of weight.

6. **Errors in Diagnosis of Pulmonary Tuberculosis.**—J. B. Hawes discusses certain sounds, not due to tuberculosis or any other pulmonary disease, but to physiological processes, which sometimes lead to confusion in the diagnosis of pulmonary tuberculosis. These sounds may cause errors in diagnosis, either by simulating râles or else by obscuring the breath sounds or such râles or other abnormalities as may be present. Muscle sounds were a potential source of error in 9.2 per cent. of the author's 250 cases. Such sounds occur particularly in muscular persons of nervous temperament. These sounds can be lessened by quieting and calming the patient and by seeing if the examining room is sufficiently warm. Errors due to these sounds can be avoided only by great care and concentration on the part of the physician. Joint sounds resembling râles and a potential source of error occurred in 22 per cent. of this series. Errors due to this cause may be avoided by the procedure of making the patient go through the motions of breathing without taking a breath. This should be done in every doubtful case. Tendon or bursal sounds, atelectatic râles, or marginal sounds ought not to cause confusion or be sources of any mistakes in diagnosis.

2. **The Determinants of Tabes.**—W. J. M. A. Maloney states that cases of syphilis are vastly more numerous than those of tabes; that tabes, far from being an inevitable, is a rare sequel of syphilis. A syphilitic protozoon may acquire a special power to attack the nervous system, and this power may be transmissible through successive generations of spirochetes and may persist in passage from host to host. The spirochete thus becomes a nerve spirochete. This so-called nerve spirochete may be a spirochete which has acquired abnormal resistance to the human defense agents; or a spirochete which is introduced as spores, which, owing to cultural characteristics acquired in the previous host, can now only or best germinate in the tissues of the central nervous system; or a spirochete in a host who, owing to individual, familial, or racial characteristics, has an imperfect resistance. The perfection of the resistance is not directly dependent upon or parallel to the local proliferative reaction; tabes may follow lesions of an ordinary or extraordinary character, or lesions of insignificant severity, or even infections which have produced no known lesions. The resistance of a host to a spore-forming organism which may invade the body tissues in succession probably depends upon the correlation of the local reaction and the biological chemical reaction of the body. This correlation probably is under the control of the autonomic and sympathetic nervous system and is achieved mainly through the medium of the ductless glands. The chemical affinities of the nerve tissues are at least as important as are anatomical relations in the distribution of syphilitic lesions throughout the central nervous system. The tabetic toxin acts as a vagotonic substance, and its action may be reinforced by autogenous and exogenous vagotonic substances. The nature of the spirochete, of the correlation of the activities of the ductless glands, and of the biological peculiarities of the chemical composition of the central nervous system determines whether or not syphilis in a given individual will result in tabes.

3. **The Alien and Infectious Disease.**—L. L. Williams believes that there is an unnecessary percentage of morbidity and a corresponding unnecessary percentage of mortality from infectious disease among immigrant children. A large number of persons infected with various acute contagious diseases pass through the immigration stations while in the incubative stage of these diseases. There is now no practicable method of effectively preventing this influx of disease. While this influx of contagion cannot be altogether stopped, it can be greatly reduced by amending and strictly enforcing the navigation laws, and by a reasonable increase of the appropriation for caring for aliens at immigration stations.

7. Pellagra with Late Skin Lesions. T. Frazer.

4. **Spontaneous Rupture of the Healthy Esophagus.**—I. J. Walker states that this condition is most frequently seen in men who are addicted to alcohol. In practically every case rupture has followed vomiting or retching after an abnormally large meal. The point of rupture in every case has been just above the diaphragm. Difficulty in making an early diagnosis in this condition is due to the fact that the symptoms are referred to the upper abdomen and not to the esophagus. The patient is in a state of marked shock with subnormal temperature, high pulse, profuse sweating, and some cyanosis. The respirations are usually slightly elevated. The face is drawn and anxious and the patient lies or sits with the knees drawn upward. Pain is referred to the epigastrium and lower chest, either on the right or left, but usually the latter. There is

marked tenderness and board-like rigidity throughout the upper abdomen. Chest examination may show a few râles at the base and sometimes hyperresonance or flatness on percussion, depending on whether there is much air or fluid in the pleural cavity. The picture up to this time is that of acute perforation of a gastric or a duodenal ulcer or acute pancreatitis. As time goes on, and especially if the patient has swallowed any liquid, the symptoms point more to some chest condition. The respirations become rapid and shallow, and the temperature elevated. The chest signs become more pronounced and the heart pushed towards the right, and the area of heart dullness practically obliterated. Aspiration of the chest will reveal fluid and gas. If the former is examined microscopically, food particles may be distinguished. In some cases there will be emphysema of the chest and neck. Very little except palliative measures can be found in the literature concerning treatment of this condition. It does seem possible that should the diagnosis be made early, there might be some chance of saving the patient by approaching the lesion through the posterior mediastinum, repairing the rent, and draining the mediastinum and pleural cavity.

5. **Salvarsan in Treatment of Syphilitic Nervous Disease.**—C. B. Craig and J. Collins reach the following conclusions: The treatment of syphilitic nervous diseases without the Wassermann reaction and spinal-fluid analysis is guesswork. The nervous system may be the site of attack within a few weeks after the initial lesion appears. The earlier antisyphilitic treatment is instituted in syphilitic nervous diseases, the greater the probability of complete recovery. Salvarsan is the most potent remedy in our armamentarium in the treatment of syphilis of the nervous system. Salvarsan is not all-sufficient. One or two doses are not usually sufficient to effect a cure, but may check the disease for a time. Syphilitic nervous diseases improve most when salvarsan therapy is combined with mercurial treatment and general tonic measures. Therapy should be continued, if possible, until the serology is negative. The serology should be determined periodically after a negative status has been achieved.

1. **Changes in the Reaction of the Blood.**—F. G. Hopkins concludes that the hydrogen ion concentration of the blood is a variable, but the interests of the body demand that its variations should be confined within a very narrow zone of change. In the maintenance of its mean value, which is such as to make the blood a very neutral fluid, a great number of factors play a part, some chemical, some physicochemical, and others more purely physiological. When appreciable variations occur they produce striking effects, especially upon the mechanism of respiration. Considerable departures from the normal indeed can only exist when the sensitivity of the respiratory center is simultaneously modified. In the tissues—at any rate, in certain tissues—wider variations in the hydrogen ion concentration probably occur, but metabolic processes are nicely adjusted to the maintenance of approximate neutrality even in the tissues themselves. Any local change of reaction when it occurs may profoundly affect the general chemical equilibrium in a tissue or organ. It is remarkable that the acidosis produced by such factors as are involved in taking exercise at high altitudes should induce more change in the actual reaction of the blood than the severer forms of acidosis occurring in a disease like diabetes. Doubtless the more gradual establishment of the acidosis favors a more complete adjustment. One has very definite evidence that variations of reaction may occur in disease and be responsible for certain symptoms, but the whole question of the range of variation in pathological states and the effects correlated with it remains for further study by modern accurate methods.

3. **The Aerial Conveyance of Infection.**—F. H. Thomson and C. Price treated certain infectious diseases in an ordinary ward with the precautions of cloak-wearing, cleanliness, and sterilization. They believe that the infection of measles is probably airborne early in the disease, but that the power of infection soon passes. They also believe that the infection of chickenpox is air-borne early in the disease, but their experience goes to suggest that on and after the third day it is probably not air-borne; in their view this probability is the most interesting outcome of the work. For many years the authors have held that diphtheria infection is not air-borne. No cross infections arose from German measles or from mumps, but the small number of cases treated scarcely warrant any definite conclusion. On the whole, however, from this and previous experience in other wards, the authors tend to the view that these diseases are probably not air-borne.

4. **The Experimental Production of Purpura in Animals.**—J. C. G. Ledingham states that during the past few years a considerable amount of attention has been directed to the part played by the blood platelets in the process of blood coagulation and to the significance of abnormal blood plate counts in those clinical conditions which have been grouped under the general heading of the hemorrhagic diathesis. The author found that a condition resembling purpura and presenting other features of the hemorrhagic diathesis can be produced in guinea pigs by inoculation of an autoserum prepared by immunizing rabbits with guinea pig blood plates.

7. **The Urinary Diastase Test and Loewi's Reaction in Pancreatic Lesions.**—L. Humphry notes that among the more recent laboratory tests which have been introduced for the diagnosis of pancreatic disease, the quantitative estimation of diastase in the urine and Loewi's mydriasis reaction are easily and promptly carried out, and the question of their value in diagnosis can be

solved only by trial in a number of cases. The urinary diastase test does not appear to have received sufficient attention. In a paper on amylolytic ferments in the urine, Dudley Corbett, following Wohlgemuth's work, describes fully the technique for making this estimation. He finds that the amount of starch-reducing ferment passed in the twenty-four hours is fairly constant, the *d* value or index being 10 to 20 units, each unit representing 1 c.c. of 0.1 per cent. starch solution converted into dextrine in half an hour by 1 c.c. of urine. The values found in the urine are not affected by ordinary changes of diet in adults, by the reaction of the urine, or by the presence of bacteria or other abnormal constituents except blood, the ferment being also present in normal blood serum, in fact, provided the kidneys are healthy, the index value of any given twenty-four hours' specimen of normal urine keeps so closely within certain limits, that for clinical purposes no greater accuracy is required. In a variety of cases of disease examined by the author high readings were found in all cases of undoubted pancreatic disease, and also in certain acute infective conditions without pronounced renal damage and in some forms of eclampsia. Loewi's test is now well known. A few drops of a solution of suprarenal extract of 1 to 1,000 strength are instilled into the eye, previously examined to ascertain that the cornea is intact. If dilatation of the pupil takes place within an hour the test is positive. In cases of pancreatic insufficiency, and occasionally in Graves' disease the test is positive. Beyond the fact that in these cases there is an increased susceptibility of the sympathetic to stimulation by the suprarenal extract, there is no known explanation of the reaction.

8. **Acidosis Terminating Chronic Myocardial Disease.**—C. Coombs reports two cases of chronic myocardial disease in which the terminal phase was marked by clinical evidences of acid intoxication (acetone smell in the breath, "air hunger," dyspnea, thirst, and cerebral symptoms). This acidosis was apparently not of the type associated with diabetes and other well known disorders, in that the B-hydroxy acids were not present in excess in the urine. Neither alkalies nor oxygen inhalations had any effect on the course of this intoxication.

10. **Dyspareunia and Its Surgical Treatment.**—J. Phillips notes that quite a number of women suffer more or less severe pain during coitus, that this condition underlies many a case of otherwise unaccountable neurosis, and that it nearly always depends on some pathological lesion which, if properly diagnosed and treated, can generally be cured. The cause may be an unruptured hymen, a hymenal fissure, kraurosis vulvæ, or vaginismus. Dyspareunia associated with vaginismus is by far the most difficult condition to relieve. The author has never been able to cure a case in which it has persisted for several years. The treatment includes: (1) A cure of any obvious pathological condition. (2) Forcible and very thorough stretching of the genital passage under full anesthesia. (3) Lubricating and anesthetizing the vagina by glycerin and cocaine prior to coitus. Other causes of dyspareunia are a retroflexed uterus, a prolapsed ovary, an ovarian cyst, ovariosalpingitis, and parturition trauma.

11. **The Trypanosome of Sleeping Sickness.**—W. Yorke and B. Blacklock present the following facts in favor of the view that game is the reservoir of human trypanosomiasis in South Central Africa: (1) Human beings and game are known to be infected with trypanosomes identical as regards morphology, pathogenicity in laboratory animals, and their development in *G. morsitans*. (2) The human trypanosome can be successfully inoculated into game. (3) The peculiar sporadic occurrence of the disease in human beings suggests that they were infected from a widely spread reservoir of the infection (the game) rather than from one another.

4. The Place of X-rays in the Treatment of Cancer.—F. Fowler believes that all cases of carcinoma of the breast, lip, or tongue should receive efficient *x*-ray treatment for prophylaxis immediately after operation. In the treatment of secondarily infected glands *x*-rays are preferable to excision. Efficient treatment is able to prevent local recurrence, mediastinal infection is rare, and ulceration should not occur.

6. Anesthetizing the Larynx.—C. Yorke concludes that anesthesia of the larynx by novocaine injections around the internal laryngeal nerves is of value: (a) When cocaine will not induce complete anesthesia, as in inflammatory and highly irritable conditions of the larynx; (b) when deep anesthesia is required, as when using the actual cautery; and (c) when the patient is unduly sensitive to the toxic properties of cocaine.

Berliner klinische Wochenschrift.

June 8, 1914.

Prognosis of Morphinism.—König states that nearly all cases of chronic morphinism consult neurologists. Prognosis is concerned both with the cure of the habit and the possibility of a relapse. In the first case prognosis is good save in very long standing examples with very large dosage. In the second case authorities differ, but only in degree. All look upon the prognosis for relapse as bad, but there is latitude here for many different opinions. The pessimism is founded on statistics, since the majority of cases are known to relapse. Favorable prognosis thus hinges about a small fraction of the victims. The conditions of a good prognosis must refer to total length of addiction, number of relapses, degree of tolerance to the drug, amount of daily dose and constitution of the sufferer—for example, should he be addicted to other drugs, should he have organic disease, should he be already a psychasthenic or neurasthenic. To this we must add the nature of the painful ailments, which first caused the use of the drug, for *ceteris paribus*, the prognosis of the painful disease shows a certain parallelism with that of the morphinism. Under this head of painful affections are comprised ordinary neuralgias, tabetic pains, peritoneal adhesions, gall and kidney stones, insomnia, and all conditions of psychical malaise, such as the "blues," worry, and the like. We thereby in the last category come upon a something which may be said to predispose to the use of the drug, and as a matter of fact a very large proportion of these cases of psychopathic constitution, with alternation of disposition, make up the morphine addicts who consult the medical man. Naturally they resort primarily to the drug during the phase of depression. But the apparently robust subject can readily as a result of the habit become a victim of acquired neurasthenia, so that at first sight it is difficult to distinguish between the two types, al-

though in the second the prognosis should be much more favorable. Many paradoxical findings are available for citation. Thus frequent relapse is, according to some observers, a relatively favorable prognostic, showing that the subject has never been a true addict. This is in accord with common sense: thus, a man once freed from the habit returns to it tentatively under manifold checks, and his second addiction is less masterful.

Anemic Erysipelas.—Von Czyhlarz contributes a note on this subject; the condition, however long known, is practically absent from literature. The author has seen three cases within as many years. One he narrates in part as follows: A girl of 20 came under treatment for erysipelas of the face, in all respects typical. In addition the patient had had several previous attacks. The blood count is not given for this particular case, but in another of the same clinical type there was present at the fever crisis a marked leucocytosis. The three cases cited were typical of erysipelas clinically, and the fall of the fever was synchronous with abatement of the redness and swelling. The blood changes before and after the febrile crisis are barely mentioned and mean nothing. The author seems to have invoked the known coincidence of pernicious anemia and erysipelas, and other phenomena, a foundation for the concept of anemic erysipelas. As has often been said in other connections, "Why should not an anemic subject develop erysipelas?"

Münchener medizinische Wochenschrift.

June 2, 1914.

Dystrophia Adeposogenitalis.—Weicksel reports a case of this infirmity, the nature of which is still obscure, despite the fact that it is associated with the hypophysis. Before describing this case the author alludes in passing to a second, transitory case, of ordinary obesity conjoined with polyuria insipida. Such a case was at best of doubtful nature. The actual case occurred in a youth of 15½ years. An older sister is not normal psychically, a fact of some significance. The patient began to flesh up when 10 years old and the corpulence has increased steadily from year to year. The progress of the child in school was not what it should have been, but there was no imbecility. Fatigue after slight exertion was pronounced. On inspection the distribution of the fat was seen to be as follows: Breasts, abdominal region, thighs and neck. Thyroid readily recognized. No persistent thymus, no enlarged lymphnodes. Skin dry. Little or no hair in axillæ and pubis. Genitals of infantile character, testicles size of beans. Head unusually small, fundus oculi normal, likewise visual acuity. Reflexes normal, as are other usual tests. Clinically, at least, the case was one of dystrophia adiposogenitalis. It remained to connect the author's case with some abnormality of the hypophysis, such as had been encountered in other cases of dystrophia adiposogenitalis. In the author's case there was no participation of the sella turcica. Hence, at a stroke, a distinction is set up between the latter and the original Fröhlich type. The blood count in the two conditions, however, seems to differ decidedly. Thus in the Fröhlich type this is very simple. The more, however, we depart from this type the greater the diversity of the blood picture—until, indeed, a *reductio ad absurdum* impends. The aim of the author is evidently to awaken interest in the minds of the profession concerning this class of cases.

Treatment of Whooping Cough.—As is well known, preparations of thyme have long been advocated for this affection. They grow in certain regions of the Old World, and have been sold in the United States at very high prices. Various derivatives of thymin have been used in different localities with good results. One combination comprises herb of thyme and the so-called "pilka"—an herb which grows wild in the same vicinity. If this compound is given in one or more doses, morning and evening, the patient "recovers" in due time, but the interval between the administration of the remedy and the cure may be so long as to render the curative action a matter of speculation.

Deutsche medizinische Wochenschrift.

June 4, 1914.

Occult Hemorrhage in Ulcer of the Stomach and Duodenum.—Boas states that the center of gravity in the diagnosis of these lesions is to be found in occult bleeding. Positive blood-finds, when permanent and associated with the rest of the symptom-complex, show the presence of a florid ulcer; while a permanently negative blood find might mean at most a cicatrized ulcer, but is relatively a negative find. For a diagnosis of an ulcer without hemorrhagic erosion the weak catalytic tests hardly answer. The author's modification of the phenolphthalein test is our only resource for the detection of minimal traces of blood in the feces. As soon as occult hemorrhage has been recognized in its inception an indication is at once supplied for early treatment; and as in other situations, a relapse can be detected at an early moment and easily jugulated. Thus far, Boas maintains, we are absolutely unable to diagnosticate by this test between ulcus ventriculi and ulcus duodeni.

Roentgenological Recognition of Ulcus Duodeni.—Schlesinger states that in only a fraction of cases does a radiogram in ulcus duodeni show distinct alterations in the duodenum. As a rule, ulcus duodeni exerts an intensive reflex action on the functions of the stomach. This action is not, as is commonly supposed, an alternating one, but is throughout directed toward the increase of gastric functions. There does not exist a so-called ebb and flow in gastric activity. On the other hand it has been assumed that the ulcer exerts a certain reflex activity, which may persist for a long time, until there develops certain anatomical alterations. The primary finds are increased peristalsis, hypertonia—especially at the pylorus, along with hypersecretion—and second, certain obstructive symptoms, which in the end amount to gastrectasia. Naturally so complicated a subject must be left unsolved with our present resources.

Salvarsan as an Abortive of Syphilis.—Hoffmann concludes as follows: The early diagnosis of this disease makes possible, according to all appearance, the abortive cure. This may be attained by a strongly combined salvarsan mercurial-ointment cure as measured by the curve of the WaR, which should be carried out rather strongly than weakly. For a permanent result there should be used 42 inunctions of mercurial ointment with the addition of from 4 to 6 (occasionally from 7 to 8) injections of old salvarsan. These must be controlled (1) by one exact clinical and serological supervision; (2) by excision of the scar of the chancre, after the treatment by research and test for the spirochete in darkfield illumination and by inoculation tests, and (3) by provocatory infusion of salvarsan in the cord five months later, with subsequent testing (after 10 days) of the lumbal punctate. If there follows a quiescent 18 months' period the patient may be regarded as cured, although a secondary provocative injection may be tried.

Insurance Medicine.

American Association of Medical Examiners.—At the fourteenth annual meeting of this Association, held in Atlantic City, June 22, 1914, the following officers were elected: *President*, Dr. A. T. Gaillard, Medical Referee, Travelers Insurance Company, Philadelphia, Pa.; *First Vice-President*, Dr. Wm. W. Tompkins, Charleston, W. Va.; *Second Vice-President*, Dr. J. N. Hall, Denver, Colo.; *Third Vice-President*, Dr. Einar Hansen, New York; *Fourth Vice-President*, Dr. Lewis McFarland Gaines, Atlanta, Ga.; *Secretary and Treasurer*, Dr. Foster K. Collins, Philadelphia, Pa.

Life Insurance in South Africa.—Dr. Gomann at a recent session of the Society for Scientific Insurance held at Cape Town expressed himself in part as follows: Life insurance is in such great demand in all social strata, and the activity of the solicitors is so bustling that there is a dearth, not only of examining physicians but even of medical directors who possess the requisite qualifications for their offices. It may be said in their favor that they are zealous and possess sufficient ability and judgment to reject poor risks; but they are unequal to the much more difficult task of discriminating between those who are really healthy and those who only seem thus. This phase of insurance medicine is not taught in schools—in fact this applies to prognosis as a whole. The medical director does not see the risks, and hence no real checking system exists. Correspondence and renewed examinations by the original examiner or a colleague are unprofitable. Any new facts of significance do not compensate for the expense nor for the changed state of mind of the risk, who may think that he is being persecuted. It is surely enough, he feels, to have to lay bare his entire family and personal history because he has applied for insurance chiefly out of friendship for the solicitor.

The attempts to recall the causes of death in the grandparents, what value do these possess? "Died old" is the best they can say. Their knowledge of the causes of death in parents, brothers, and sisters is usually vague; and they appear to have an instinct towards misrepresentation when they have actual knowledge of the deaths, lest their chance for acceptance be prejudiced thereby. Especially are they silent in respect to tuberculous relatives. Family pride may step in—who would admit that his father shot himself after a defalcation, or that his mother died in the poorhouse?

The same attitude appears in the personal history. Whether or not coached by the agent the risk usually makes a general denial as to previous diseases. These negative denials may be made in good faith. In the possible history of a gallstone attack, for example, the examiner may obtain only the admission of cramps in the stomach, of jaundice, etc., but the risk is honest in denying gallstones for he may have been quite ignorant of their existence.

As is known to all, the personal history in regard to the use of alcohol is *per se* almost worthless. No man can prove that he is a teetotaler. Physical examination of the chest in the short time practicable is more or less of a farce. The anxious, timid applicant often creates a bad impression based on a number of peculiarities.—*The Medical Director.*

The Significance of a Diabetic Family History.—In a paper read by Dr. Otto May, on March 4, 1914, before the Life Assurance Medical Officers' Association of Great Britain, it was pointed out that it is a commonly accepted belief that diabetes is in many cases a "family disease," *i.e.* one which is prone to occur in several members of certain families, in greater proportion than would be expected if its distribution were uniform throughout the population. If this be so it becomes a question how far, if at all, one or more deaths from diabetes in a family history should influence our recommendations on the proposed life. An analysis of the investigations undertaken by May suggests that: 1. There is a form of "family diabetes" tending to occur at an earlier age, and proving fatal more rapidly than the ordinary "acquired" type of the disease. 2. This family diabetes is more likely to occur in the male than in the female. Therefore, says May, an attempt may now be made partially to answer the question propounded at the beginning of the paper as to what weight, if any, should be attached to the presence in the family history of one case of diabetes. Since only 3.6 per cent. of the death claims from diabetes show this "positive" history, May thinks it probable that the actuary would feel it hardly justified or worth while to rate-up in these cases. If, however, the diabetic death is in a young male, and especially if, with this, the proposer is a male under forty, then he holds that the question of "rating-up" should be seriously considered.

Benefit of Reexaminations.—Bart. E. McKenzie, Medical Director, Policyholders' Mutual Life Insurance Company, Toronto, Ont., considers it a most valuable suggestion that the policyholders should be asked and encouraged to present themselves for re-examination. In one case a policyholder presented himself for examination and was told that his condition was not entirely satisfactory. As a second insurance was desired, he was examined again, but it was found to be impossible to give him a policy as favorable as the first one. He was offered one at a higher cost and it led him to think over the matter of health. As a result business was relinquished, and a few weeks were spent in the effort to win back a favorable condition of health. The experiment proved a benefit to the individual, and, consequently, to the company.—The Association of Life Insurance Presidents, December, 1913.

Health Insurance—Construction of Policy.—A health insurance policy provided for the payment of indemnity in the event the assured, under certain specified conditions, suffered from any of the diseases enumerated therein. Among these diseases were "nephritis" and "acute meningitis." The policy declared that it did not cover any chronic disease, or any disease in other than acute and fully developed form. The assured, being afflicted with chronic nephritis, sued the company under the policy. He contended that because the disease of meningitis was named in the policy "acute meningitis," and that the word "acute" was not used with reference to nephritis, therefore it was the intention of the company to insure him against nephritis in any of its forms, either acute, chronic, or otherwise. It was held that, taking the whole contract together, any one suffering from any of the diseases named in the policy was not within the intention of the parties to the contract, and the insured was not entitled to recover.—Kingkade v. Continental Casualty Co., Oklahoma Supreme Court, 128 Pac. 683.

Book Reviews.

Biochemic Drug Assay Methods, with Special Reference to the Pharmacodynamic Standardization of Drugs. By Paul S. Pottenger, Ph.G., Ph.C., Phar.D., Instructor in Pharmacodynamics, Medicochirurgical College, Philadelphia. Edited by F. E. Stewart, M.D. Ph.G., Professor of Materia Medica and Botany, Medicochirurgical College of Philadelphia. Price $1.50 net. Philadelphia: P. Blakiston's Son & Co., 1914.

This volume deals exclusively with a class of drugs which is not amenable to chemical standardization. This group includes digitalis, aconite, apocynum, convallaria, squills, strophanthus, epinephrine, gelsemium, veratrum, ergot, pituitary extract, and cannabis indica. It is intended primarily for the use of experts in laboratories devoted to drug standardization, but may be used advantageously as an aid in the instruction of students in medicine and pharmacy. Apparatus is fully illustrated and the methods are described in detail. There are many excellent illustrations. The book should prove very valuable to workers in this field.

The Biology of the Blood-Cells, with a Glossary of Hemotological Terms, for the Use of Practitioners of Medicine. By O. C. Grüner, M.D., Assistant Professor of Pathology, McGill University. Price $6.00 net. New York: William Wood & Company, 1914.

In spite of the assurance of the title it hardly seems likely that the general practitioner of medicine will be much attracted by this work. It is a highly technical discussion of the numerous theories of the biology of the various cellular elements of the blood and necessarily employs a special vocabulary. Its chief value will perhaps lie in the presentation of these theories, in which respect the work is very complete. When the author comes to present his own conclusions, however, he will find many readers who will fail to agree with him. To consider these separately would lead to endless and fruitless discussion since in few instances is the truth demonstrable. One feels that the author is apt to be too dogmatic, as a rule too sure of the correctness of his position. The work is, however, an excellent reference book for those interested in this particular line of study.

De la Néphropexie (Procédé d'Albarran-Marion), par le docteur Jules Luzoir, Ancien Interne des Hôpitaux de Paris, Aide d'Anatomie à la Faculté de Paris. Paper, 270 pages, with 49 illustrations. Price 8 francs. Paris: G. Steinheil, 1913.

After a short introductory chapter, Luzoir devotes about 80 pages of this thesis to quotations from important papers by numerous authors which have appeared during the past 25 years, thus giving a review, in chronological order, of the opinions that have been held as to the indications for treatment of a movable kidney and the comparative value of the operative and non-operative methods of handling these cases. He has succeeded admirably in showing the fluctuations of sentiment in this regard. A short chapter summarizes the indications for operation, then the author reviews all the operative procedures of which he could find record from the time of Hahn, who in 1881 did the first nephrorrhaphy, to the latest methods of Kocher and Henschen, who in 1913 reported the use of free fascial flaps in the fixation of a movable kidney. About 60 pages are devoted to the description and illustration of these procedures and among them we find the methods of Morris, Edebohls, Guiteras and several other American surgeons described and illustrated, while those of many other American operators are more or less fully reported. The author then summarizes the various types of operations and discusses the different points that have been raised, such as the relative value of high and low fixation, suture material, drainage, and the procedure of choice, which he considers to be that of Albarran as modified by Marion. A critical review is then given of thirty-five cases operated upon by this method. This is followed by a résumé of observations and results and the author's conclusions. The book is very interesting and gives by far the most complete presentation of the subject that has appeared in recent years. Those who think they have devised a new method for anchoring a movable kidney should read this thesis before publishing it, for the chances are that the principal, if not complete details, will be found noted here.

Le Traitement de la Syphilis en Clientèle "L'indispensable en syphiligraphie." By H. Gougerot, Professeur Agrégé a la Faculté de Médecine de Paris. Paper, 492 pages, with 53 plates, of which 12 are in colors. Price 10 francs. Paris: A. Maloine, Èditeur, 1914.

This book is based upon and contains the substance of a series of lectures delivered at the Hôpital Saint-Louis. As the author says in the preface, "No branch of medicine * * * brings up more difficult problems of diagnosis, of therapeusis, and of prognosis than syphilis," and while the large treatises are encumbered with too much detail for the average practitioner, most of the smaller works are deficient in therapeusis or some other important factor; so that it is hard for the non-specialist to find in a single volume all the information that he requires for the proper diagnosis and treatment of these cases as they occur in private practice. Gougerot has attempted to fill this need by incorporating all that is useful in the diagnosis and treatment of these cases, and leaving out all that is not indispensable, such as references to the anatomy, pathology, statistics, etc. All practical questions have been touched upon if not fully elaborated. The order of presentation and some of the subjects covered in this book are quite different from those found in the ordinary treatise. The style is in accord with the relations of teacher and pupil, and the author gives advice upon many unusual topics, such as the manner of revealing the diagnosis of syphilis; the proper conduct of the physician when the patient is married, a child, or a domestic; how to treat cases where the nature of the initial lesion is still doubtful—all in a rather intimate conversational way. The author then takes up in detail the description and diagnosis of the various stages of the disease as it affects the skin, mucous membranes, and all the different tissues and organs, differential diagnosis, treatment, etc. All these subjects are well covered and often in a most minute detail, thus thoroughly meeting the requirements of the general practitioner, and furnishing an unusually complete résumé of the important points in this most complex disease.

Treatment of Chronic Leg Ulcers. A Practical Guide to Its Symptomatology, Diagnosis and Treatment. By Edward Adams, M.D., Instructor of Surgery, New York Post-Graduate Medical School and Hospital. Price $1.00. New York: The International Journal of Surgery Co., 1914.

It has been said that if any young surgeon will take the trouble to study and treat carefully and scientifically all cases of leg ulcer which come to him he will soon acquire an enviable reputation and an extensive practice. Certain it is that as a general thing leg ulcers are considered undesirable and receive only routine treatment. There has been no book on the subject and the text-books on surgery usually mention them only briefly and in a casual fashion. This book is therefore a very welcome addition to medical literature. The author has covered the whole subject thoroughly and systematically and any physician will read it with profit. The volume is excellently illustrated with photographs.

Immunity. Methods of Diagnosis and Therapy and Their Practical Application. By Dr. Julius Citron, Assistant at the University Clinic of Berlin, II. Medical Division. Translated and Edited by A. L. Garbat, M.D., Assistant Pathologist and Adjunct Visiting Physician, German Hospital, New York. Second Edition. P. Blakiston's Son & Co. Price $3.50 net. Philadelphia, 1914.

The second edition of this translation appears within two years after the first and allows the insertion of the newer advances in immunity. The text has been revised to advantage in a number of instances and the few typographical errors of the first edition corrected. The discussion of small-pox and antityphoid vaccination has been enlarged and a number of new subjects introduced. The most important of these are gonococcus and typhoid complement fixation tests, agglutination and hemolysis tests for transfusion, a more detailed discussion of anaphylaxis and an account of studies of cancer in their relation to immunity. All the changes tend to increase the value of the book which remains probably the best work of its size on the subject in the English language.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixty-fifth Annual Meeting, Held in Atlantic City, June 22, 23, 24, 25, and 26, 1914.

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 1196, *Vol.* 85.)

HOUSE OF DELEGATES.

Thursday, June 25—Fourth Day.

THE PRESIDENT, DR. VICTOR C. VAUGHAN, IN THE CHAIR.

Report of Reference Committee on Medical Education.—This committee recommended for adoption a resolution calling for an investigation of the conditions under which the degree of Doctor of Public Health and Sanitation and similar degrees were being conferred and to make a report next year. This resolution was adopted.

Report of Reference Committee on Health and Public Instruction.—This committee reported that the resolutions of the Section on Dermatology with reference to the Federal control of lepers in Interstate Commerce and provision for the proper care of those affected with this disease by the Federal Government was recommended for adoption by the House. This committee also recommended the adoption of the resolutions urging that efforts be made to secure legislation designed to make general the adoption of the milk standards and classification of the New York Milk Commission in all communities in the United States in so far as local conditions would permit. They further recommended the adoption of the resolution calling for a proper labelling of lyes and all caustic substances used in cleansing preparations. The House of Delegates adopted these resolutions.

Report of Reference Committee on Constitution and By-Laws.—This committee presented resolutions asking that the Committee on Constitution and By-Laws be instructed to draft an amendment to the Constitution and By-Laws providing for the change in time of meeting of the House of Delegates in accordance with the resolutions that had been adopted providing that hereafter the House of Delegates should meet on the Saturday preceding the week of the annual meeting of the American Medical Association. This resolution was adopted.

Report of Reference Committee on Legislation and Political Action.—This committee expressed itself as impressed by the scope of the work of the Council on Legislation and Political Action, and commended the plan outlined in their report for a general survey of public health conditions and activities throughout the world which would furnish data invaluable in elaborating plans for a national Health Department. They also approved the plan for the investigation of the subject of expert testimony and that the committee draft a bill suitable for presentation to state legislatures and report at the next meeting. It was recommended in addition that the publicity committees which it had been decided to appoint in each county society to see that medical news was properly presented to the lay press be appointed by the state societies and be under their jurisdiction. They further recommended the adoption of the resolution urging the enactment of Federal legislation for regulation of the manufacture and sale of bichloride of mercury tablets. This report was adopted.

The Scientific Exhibit.—It was the opinion of those capable of judging that no previous exhibit had equalled this one in point of scientific interest. The seventeen research exhibits were demonstrated more or less continuously, and additional slide demonstrations were given each morning and afternoon. The exhibits embraced a wide scope of subjects, among which were: Experimental Hydronephrosis: Effects upon the Kidneys of Dogs of Collargol Injections. Hereditary Factors in Mice Cancer. Relation of Diet to Tumor Growth. Relation of Gastric Ulcer to Cancer, Lateral Blood Vessel Anastomosis in the Cure of Arteriovenous Aneurysm. Showing Communication of Erythema Nodosum to Dogs. Results of Chronic Lead Poisoning on the Liver in Guinea-pigs. The Effect of Feeding Pituitary Extract in Hastening Genital Development in Rats. The *X*-ray in Relation to the Diagnosis of Diseases of the Thorax and Gastrointestinal Tract. The Toxemias of Pregnancy. The scientific exhibit from the Mayo Clinic consisted of two divisions: First, that from the Roentgen laboratory, consisting of roentgenograms and stereoscopic slides of specimens removed at operations, illustrating lesions of the gastrointestinal tract. Second, that from the pathological laboratory which consisted of photographs and drawings illustrating work in progress on the mode and development of cancer, the pathological relationship of gastric ulcer and carcinoma, a study of the possible relationship of gastric ulcer and carcinoma, a study of the possible relationship of renal carcinoma and nephrolithiasis, and studies in the pathology of the atrophic kidney.

Attendance.—The registration up to Wednesday evening, June 24, was 3833 for the three days.

SECTION ON PRACTICE OF MEDICINE.

Thursday, June 25—Third Day.

Election of Officers.—*Chairman*, Dr. Thomas MacCrae of Philadelphia; *Vice-Chairman*, Dr. John L. Dawson of Charleston, S. C.; *Secretary*, Dr. Roger S. Morris of Clifton Springs, N. Y.; *Delegate*, Dr. Richard C. Cabot of Boston; *Alternate*, Dr. E. E. Irons of Chicago.

End Results of Cases of Gastric and Duodenal Ulcer.—Dr. ELLIOTT P. JOSLIN and Dr. HUGH P. GREELEY of Boston presented this communication. They offered the following conclusions: 1. In a study made of 234 consecutive cases of gastric and duodenal ulcer seen in private practice during the last sixteen years, 213 cases or 91 per cent were treated to date. 2. 142 were males, 92 females. 3. The average age of the males was 45 years and eight months, but the age at onset was 38 years and eight months. The average age of the females was 36 years and four months, but at onset 30 years and 10 months. The average duration of the ulcer in the cases still unrelieved was 11 years. The average duration of the ulcer before the cases reached the surgeon was 10 years. 4. One hundred and thirty-one cases were traced who were treated surgically throughout and of these at present 51 or 39 per cent. were well, 55 or 42 per cent. were relieved, 16 or 12 per cent. were unrelieved, and nine or 7 per cent. were dead. 5. Eighty-two cases were traced who were operated upon when medical treatment had failed and of these cases 33 or 40 per cent. were well, 13 or 16 per cent. were relieved, 10 or 12 per cent. were unrelieved and 26 or 32 per cent. were dead. 6. Deducting 12 deaths for which the surgeon should not be held responsible, there were 70 surgical cases of which 33 or 47 per cent. were well, 13 or 19 per cent. were relieved, 10 or 14 per cent. were unrelieved and 14 or 20 per cent. were dead. 7. The combined medical and surgical results showed at present the following: well, 84 cases or 39 per cent.; relieved, 68 cases or 32 per cent.; unrelieved, 26 or 12 per cent.; dead, 35 or 16 per cent. 8. Twelve or 6 per cent. of the 213 cases died of cancer, but of the 46 cases now dead the mortality from cancer was 26 per cent.

Gastric Cancer in the Young: A Study of Sixteen Cases in Patients Under the Age of Thirty-one Years.—Dr. FRANK SMITHIES of Chicago read this paper. The 16 instances of gastric cancer in the young, forming the basis of his report, occurred in his study of the records of 721 pathologically demonstrated cases of cancer of the stomach. He thought that this analysis might develop certain facts which would be of service in anticipating or detecting this malady at the age when it was least expected. There were nine females and seven males. The youngest age was 18 and the oldest just past 30 years. The average age was 28.7 years. Twelve patients were married. In two instances there was a family or blood relationship history of cancer. Useful facts were brought out by a study of the duration of all gastric complaints. The shortest time covering this phase was four months, while the longest was 15 years. The average time was 4.2 years.

Dr. J. N. HALL of Denver, Colo., spoke of the difficulty of making a diagnosis in some cases of ulcer of long standing. He had seen chronic pinched ulcer and puckered scar from old ulcers in cases that developed acute symptoms. He had seen the symptoms of ulcer associated with an alcoholic thrombosis of the superior mesenteric arteries and after operations for appendicitis due to dragging down of the omentum. Slight

herniæ and gall-bladder disease might also give symptoms suggestive of ulcer.

Dr. FRANK B. LUND of Boston, Mass., said that Dr. Joslin's paper showed the results of surgical treatment and was fairly well classified, and absolutely accurate. If he had made the statement that the operative mortality was 20 per cent. that was not to be applied to any given patient. He had admitted to his series several cases of perforation and one case that died six months after the operation that should have been excluded. These had raised the mortality rate; one might tell individual patients that the operative risks were much less than Dr. Joslin had stated.

Dr. FRANK BILLINGS of Chicago, Ill., said that by his own statement some of the patients had been seen only once in consultation and that as many as thirty surgeons had taken care of thirty patients, but he did not say how many physicians had carried out the medical treatment, or why the medical treatment had failed. Such a paper was valuable, but it would be much more valuable if we had definite statements of both the medical and the surgical treatment. The medical management as often carried out was not medical management at all and could not be used for comparison.

Dr. D. L. LICHTY of Pittsburgh, Pa., said that another point brought out by the paper was that the patients had not been seen on the average until the disease had run a course of five and one-half years. These patients had been treating themselves, taking soda mint, etc., for years, before they consulted a physician; this fault was not one of the laity alone, as many physicians in their own cases did the same thing. If all means were employed the diagnosis of ulcer was not so difficult to make during the first few months; it was only after they had gone five years that the diagnosis became so difficult. The one point that should be emphasized was that people should be taught to apply early for treatment in case of gastric disturbance. If cases came for treatment early the results of medical treatment would be better.

Dr. ALEXANDER LAMBERT of New York said that Dr. Joslin had not brought out the point when he spoke of thirty surgeons having operated on 30 cases whether the results were better or worse than when operations had been done by men in the habit of operating for this condition. In old ulcers there was not much question but that the mechanical interference of cicatricial tissue lessened the possibilities of cure by medical treatment which was of so many types and so badly carried out. If they were to reach a solution of the questions presented by these cases it would have to be through a study of the etiology.

Dr. F. A. SPEIK of Los Angeles, Cal., said that Dr. Billings was right in what he had said; the diagnosis of gastric and duodenal ulcer should be made early and the trouble should be energetically treated, and if this were done there would be fewer operations. Perforation demanded immediate recognition and treatment and the sooner operation was performed the better.

Dr. ALLEN A. JONES of Buffalo said that there was one thing that Dr. Joslin's paper brought out and that was that there should be no contention between the medical and the surgical men on this subject. Surgery was but a form of mechanical therapeutics and if the patient did not progress under medical treatment he should receive the mechanical treatment offered by surgery. As to the medical treatment of gastric and duodenal ulcer, every patient should be in a hospital under strict surveillance so that the physician should be in a position to know of every thing that went into the patient's stomach. In 556 cases medically treated by absolute rest, milk diet, poultices to the epigastrium, and with the administration of very little medicine, there were 95 per cent. of cures. He did not know the end results in these cases, but probably there were a number of recurrences.

Dr. J. R. VERBRYKE of Washington, D. C., said that the thread test and the benzidine reaction for occult blood as well as the radiograph he held of more importance than the clinical history. When a number of thread tests had always shown the blood at the same place on the thread, this had been almost infallible proof of the presence of ulcer. He rarely made a positive diagnosis of ulcer without a positive benzidine test. The speaker said he was still finding more gastric than duodenal ulcers. The localization of the ulcer was of great importance, both as regarded prognosis and the treatment chosen. A duodenal ulcer operated upon with gastroenterostomy and closure of the pylorus usually gave a spectacular result, while ulcer of the greater curvature might not only not be cured, but might even be aggravated unless excision was practiced. The patient supposed to be cured should be asked to report once a month and to bring a specimen of feces to be examined for occult blood; if a patient had no return of symptoms or of occult blood for twelve months one could consider him cured.

Dr. ANTHONY BASSLER of New York made the distinction of hard and soft ulcers. All the ulcers that were soft, whether called erosions or fissures, whether in the stomach or duodenum, would get well on medical treatment, but a vast number of ulcers began as a cicatricial process and when there was formation of cicatricial tissue there was small hope of medical treatment effecting a cure. Dr. Joslin's statistics had not been optimistic enough from either the medical or the surgical standpoint. The etiology of these ulcers should be studied, and they should be classified as good, bad, and indifferent, how treated, how long treated, when operated upon and how operated, and then they might begin to understand the subject as they should.

Dr. M. H. FUSSELL said that in reference to gastric cancer occurring under the age of 30 years, he had had three cases, one at 18 years, one at 24, and one at 30, and in every instance there was free hydrochloric acid and the total acidity was increased, and all were of the fulminating type. They were all confirmed by histological examination.

Dr. J. M. RECTOR of Columbus, Ohio, said that in all this discussion he had not heard the word "indigestion," yet most of these patients with ulcers gave long histories of indigestion and the real trouble was not recognized in many cases until the patient was beyond the help of surgery. He suggested that when a physician met a case such as had always been called indigestion he should go over the patient very carefully and find out what was the matter. When, after a certain length of time medical treatment failed to give relief, an exploratory operation should be done; this was less dangerous than prolonged medical treatment that was unsatisfactory.

Dr. ELLIOTT P. JOSLIN of Boston, in closing the discussion, said he hoped no other series would be reported in which the patients had suffered five years before seeking relief. As to the end results in surgical treatment, about 60 per cent. of the operations had been performed within the past four years, while the end results of medical treatment were based on observations covering a period of sixteen years. Dr. Joslin called attention to the large number of relapses and deaths in the earlier series of cases treated medically in the Massachusetts General Hospital where the patients were well treated, and thought it would be found about the same elsewhere.

Dr. FRANK SMITHIES of Chicago said, in closing, that this whole subject was in a stage of transition, medical men were trying to interpret surgical statistics and surgical men were trying to interpret medical statistics. The life history of these ulcers was one of remissions and exacerbations and the whole subject was very complicated. Many so-called cases of gastric ulcer in young people were cases of vagotonia or of gallbladder disease. Dr. Joslin was justified in giving such statistics as he did; he had gone as far as one could go at present. As to the thread test and the benzidine test, in 167 cases of proved ulcer they had only obtained a positive result in seven cases by the thread test. With the benzidine test the results were not to be relied upon as carrots and other vegetables gave the same reaction.

Focal Infection: Its Broader Application in the Etiology of General Disease.—Dr. FRANK BILLINGS of Chicago read this paper. It was his opinion that focal infection was very frequently related to local and general disease. The focus of infection might be located anywhere in the body but the usual site was in the head in the form of alveolar abscess, tonsillar abscess, cholecystitis, appendicitis, submucous abscess anywhere, etc. A study of the tissues and exudates of the focus yielded various bacteria. Acute rheumatic fever was of undoubted focal origin. The removal of the focus of infection was demanded as a fundamental principle in the treatment of systemic diseases especially of the chronic type.

The Newer Bacteriology of Various Infections as Determined by Special Methods.—Dr. E. C. ROSENOW of Chicago read this paper in which he described methods for making cultures from excised tissues and from the blood and other fluids in which due regard was paid to the question of oxygen pressure, particularly in the primary culture, and he detailed very briefly the results obtained by their use in various infections.

Dr. W. S. Thayer of Baltimore said that these two papers were of great importance as there had been nothing in the last fifteen years that had so changed the aspect of the practice of medicine as the recognition of the influence of local foci of infection on systemic disease. Dr. Cabot called attention in his paper yesterday to the relation of local foci of infection, such as rheumatic infections, to mitral insufficiency or stenosis. The speaker emphasized the importance of recognizing the influence of infected tonsils on systemic disease and the importance of the complete removal of infected tonsils; an incomplete operation often left the patient in a worse condition than before.

Dr. A. C. Griffith of Kansas City called attention to the discovery of diptheroid bacilli in Hodgkin's disease and of their influence. He cited a case of glandular enlargement due to this organism which was improving rapidly under treatment with autogenous vaccines. The patient went to a Christian Scientist, and, on discontinuing treatment, became rapidly worse. He saw her later when she was dying. At autopsy the glands showed the changes typical of Hodgkin's disease.

Dr. Frank Smithies of Chicago said they had been observing the seasonal recurrence of gastrointestinal diseases; these being especially marked in the spring or autumn. There seemed to be a connection between these exacerbations of ulcer, gallbladder disease, etc., in connection with such infections as were generally styled grip. In the study of 1,500 cases of gastric and duodenal ulcers 60 per cent. of the cases gave a history of an antecedent appendicitis, or gall-bladder, pancreatic, or other infection, thus showing the importance of foci of infection in the etiology of gastric and duodenal ulcers.

Dr. E. Libman of New York discussed the relation of foci of infection to the different neuroses and indicated that many of the neuroses had some infection as a basis.

Dr. Harvey D. Wood of Fayetteville, Ark., stated that he had been observing the seasonal recurrences of pellagra; it recurred usually in the spring coincident with the appearance of the bedbug and they were about to fasten the responsibility for this disease upon this parasite.

Dr. James N. Anders of Philadelphia said that what they had learned in regard to the influence of these foci of infection made it important to make it a routine practice to examine the mouth of every patient more closely than was generally the custom. Sometimes the examination of the mouth might appear to be negative but one would find metastases from this source and an *x*-ray examination might reveal concealed foci of infection in the teeth.

Dr. Alfred Stengel of Philadelphia said that Dr. Rosenow, with a modesty as great as the brilliancy of his work, had said that they were not sure that the diphtheroid organism was the specific organism of Hodgkin's disease, but he thought they had established the specificity of this organism in Hodgkin's disease.

Dr. Frank Billings of Chicago, in closing, told of the cooperative work that was being done between the laboratory men and the clinicians in Chicago. He thought the autogenous vaccines might be helpful in raising the defences of the system when there was infection and told of some of their work in the endeavor to obtain a horse serum that could be used in combating these infections.

Dr. E. C. Rosenow of Chicago cited a case of rheumatic endocarditis and pericarditis which was the effect of an ingrown toe-nail and another in which they were the result of a crushing injury to the thumb. Enlargement of glands and lymph nodes was not the result of toxemia in the blood that selected particular glands, but was the result of infection. In discussing the relation of streptococci in the borders of ulcers in the stomach to acidity, Dr. Rosenow said there was reason to believe that the acid had a tendency to destroy the organisms, and the fact that an ulcer did not heal was due to other than mere mechanical ones. In the cardiac region of the stomach the cells were acid secreting and it seemed that ulcers in this portion of the stomach healed more readily. He thought the factor of infection explained the recurrences in duodenal ulcer.

The Dead Space and Alveolar Air in Emphysema and Bronchial Asthma.—Dr. C. F. Hoover of Cleveland, Ohio, said that both bronchial asthma and pulmonary emphysema caused enlargement of the lung. Spasm of a bronchus leading to one lobe of the lung would cause an increased volume of the lobe affected. Stenosis in the larynx would cause an increased volume of the entire lung. Emphysema and asthma might be severe without modifying the respiratory function of the lung. The source of distress in both emphysema and asthma lay in the ventilating function. The degree of emphysema could be measured by the carbon-dioxide concentration in the alveolar air. This was not true in bronchial asthma.

Dr. George N. Jack of Buffalo said that thoracic emphysema and its relationship to asthma was an interesting question. Clinically uncomplicated asthmatics over fifty years of age with long standing asthma and marked emphysema responded more readily to treatment than did younger subjects where asthma was just beginning. There were many reasons other than the establishment of emphysema why old asthmatics should respond more readily to treatment than did the younger subjects, one of which was that in early life the system was rich in lymphatics, while in advanced years all the lymphatic glands and tissues atrophied and some disappeared entirely. From the emphysema side there were also many reasons. A cough forcibly shot or squirted the blood through the vascular system which resulted in a sudden dilatation of the capillaries and with more or less shock to them. A series of frequent coughs or cough paroxysms as often seen in asthma and whooping cough resulted in such congestion as to nearly if not actually equal a blood capillary stasis in the lung air cells; the mucous membrane of the air tubes and also the brain. The blood and lymph capillary congestion and stasis of the lung air cells, bronchi, trachea, larynx, and brain resulting from the violent paroxysmal "wound up to run down" cough, especially as met with in blood debilitated subjects where the capillaries were poorly nourished, resulted in a variety of conditions that were distressing and alarming if not fatal. Clinically he had observed from a study of 618 cases of asthma that the old asthmatics with pronounced emphysema responded more quickly to treatment and got a more permanent result than did the cases where asthma had recently developed or before the establishment of emphysema.

The Late Manifestations of Inherited Syphilis with Special Reference to Arterial Disease.—Dr. Henry Farnum Stoll of Hartford, Conn., read this paper and offered the following conclusions:—1. They must accustom themselves to think of syphilis as a family disease. But rarely was their patient the only one infected. 2. Over half of the children born of syphilitic parents, who survived infancy, gave a positive luetin reaction. In nearly 90 per cent. of those with obvious ailments the Wassermann or luetin test was positive. 3. There was often nothing in the appearance to suggest lues and the symptoms were indefinite and often misleading. 4. Too much emphasis could not be placed upon the importance of a complete family history in every obscure case. 5. It seemed probable that syphilis might be transmitted to the third generation. 6. Some cases of neurasthenia were due to congenital lues and could be promptly cured by specific treatment. 7. Syphilis appeared to be an etiological factor in certain of the families prone to heart and arterial disease. 8. Hypertension in middle life might be due to congenital lues. 9. Both the Wassermann and luetin tests should be employed, as neither was infallible, the Wassermann being frequently negative in syphilis hereditaria tarda, the luetin occasionally so. 10. The examination of all venereal sores for spirochetes and their prompt treatment, controlled by the Wassermann and luetin tests, would ultimately make congenital syphilis a medical curiosity.

Dr. Robert N. Wilson of Philadelphia presented two interesting specimens, the heart of a child and the heart of an adult. He referred to what had been stated that in hereditary syphilis many of the infants showed none of the ear-marks of syphilis at all characteristic, hut one should always feel the arteries. These vessels would appear to be fibrous or hardened and the patients looked like little old men or little old women. Sometimes there was glandular enlargement. But the condition of the arteries was most characteristic in a syphilitic child. When no other apparent symptoms or signs were present the feel of the arteries would often point to the true condition. One heart presented was from a child four years of age who died from a ruptured aneurysm of the thoracic aorta and in the specimen was shown an aortic and mitral stenosis. The specimen of the heart from an adult patient was similar to what was described by Dr. Stoll in his paper. The patient was a young woman, an invalid with absolute absence of any signs of any rheu-

matic affection, without pain, tonsillitis, sore throat, arthritis, or anything that would lead one to suspect rheumatism. One parent was syphilitic. He got a weak positive Wassermann reaction. The heart showed a stenosed valve which he believed to be caused by syphilis but he did not believe that it was the result of a rheumatic or a streptococcic infection, but a syphilitic sclerosis.

Various Types of Lues: A Clinical and Laboratory Study—The Abelin Reaction; Direct Subdural Injections.—Dr. WILLIAM EGBERT ROBERTSON and Dr. J. V. KLAUDER of Philadelphia presented this communication. The present conception of syphilis was that in its earlier stages it was a septicemia with more or less involvement of the nervous structures and coverings from the beginning. In the course of time, for some unknown reason, special predilection was manifested for some particular organ or tissue and after a period of apparent latency which only serological study would reveal. In some instances the latency was so well concealed that only a provocative Wassermann would reveal it. After discussing the clinical types of lues, with special reference to sphincter paresis as a definite diagnostic sign, they spoke of the value of the Abelin reaction, especially as applied to subdural work, to determine the presence of arsenic in serum and urine. They were unable to obtain a reaction in the serum of blood removed in 90 minutes in any case.

A Study of the Arneth Formulæ.—Dr. GRAHAM E. HENSON of Jacksonville, Fla., read this paper. He said that in the Arneth classification the polynuclears were divided into five classes depending upon the number of nuclei contained within the cell. His work as well as others had been confined largely to tuberculosis. Dr. Henson gave many tables showing the count in many other diseases and said that up to the present his findings would lead him to think that in certain classes of cases the Arneth Index was of some prognostic value, enough at least to warrant a careful and intensive study of the blood picture in all septic and infectious diseases.

Salvarsan in the Treatment of Pernicious Anemia.—Dr. JAMES S. BROTHERHOOD of Clifton Springs, N. Y., read this paper. After reviewing the series of cases of pernicious anemia of Bramwell and Boggs treated with salvarsan, the author stated that he had had seven cases under observation, all of which had received salvarsan intravenously. Of these five were males and two females. All were over 40 years of age. The average hemoglobin on admission was 29 per cent., the lowest being 20 per cent. and the highest 60 per cent. The average red blood count on admission was 1,100,000. Intravenous injection of salvarsan in doses of 0.4 to 0.6 grams were given at intervals of two to three weeks, the largest number of injections given to any one patient being six over a period of four months. Four of these cases were at the present time doing well, with the blood in a satisfactory condition. No untoward symptoms had followed the injections though there was sometimes a slight headache or a little nausea. It was obvious from the writer's cases and from those reported in the literature that it was too early to draw any conclusions as to the possibility of obtaining permanent improvement or cure of pernicious anemia by salvarsan. In a disease characterized by chronicity and a tendency to relapse it seemed rather improbable that such a result would be achieved. Salvarsan in a single dose was of doubtful value. The results thus far obtained in the treatment of pernicious anemia by salvarsan were sufficiently encouraging to warrant an extended trial of the drug.

The Medical Application of Blood Transfusion by the Syringe-Cannula System Without Skin Incision.—Dr. E. LINDEMAN of New York presented this communication. He stated that a study of the change of the substances in the blood in disease suggested the possibility of modifying the blood of the donor to rectify these conditions and to make more potent the agencies at work in overcoming disease. It was not only important to know when and how to apply blood therapy but equally important to know when and why not to apply it. Blood transfusion therapy might be considered in aplastic anemia, but in this disease leucoblastic and erythroblastic activity became completely and permanently paralyzed and the introduction of fresh blood was utterly inadequate to favorably modify the course of the disease. In splenic anemia with hematemesis, if syphilis prevailed and the anemia was in excess of the blood lost, transfusion would be of little aid until the patient had received antisyphilitic treatment. In simple anemia of grave degree of unknown cause, striking benefit had been obtained by blood transfusion. In gastric ulcer with hemorrhage and anemia transfusion was indicated after cessation of the hemorrhage and before operation was recommended. In severe anemia secondary to hemorrhage transfusion was specific. In alcoholic cirrhosis of the liver with severe secondary anemia the results of transfusion were good. The author had had no success with transfusion in acute leucemias. In hemophilia transfusion was the measure of choice and should be performed during the active stage of bleeding. It was sometimes a prophylactic after all bleeding had ceased. This measure was sometimes applicable in postoperative cholecystotomy and after operations for sarcoma and carcinoma. In cases of malnutrition thus far the procedure had been of little value, but where anemia was associated the results in some cases were good. Repeated transfusions might check septic processes.

SECTION ON OBSTETRICS, GYNECOLOGY AND ABDOMINAL SURGERY.

Thursday, June 25—Third Day.

DR. E. GUSTAV ZINKE OF CINCINNATI IN THE CHAIR.

Election of Officers.—The following officers were elected: *Chairman*, Dr. Thomas C. Cullen, of Baltimore; *Vice-Chairman*, Dr. George B. Somers, of San Francisco; *Secretary*, Dr. Brooke M. Anspach of Philadelphia; *Delegate*, Dr. Chandler W. Barrett of Chicago; *Alternate*, Dr. Henry Schwarz of St. Louis.

The Present Status of Pyelography.—Drs. FLOYD E. KEENE and HENRY K. PANCOAST of Philadelphia wrote this paper, which was read by Dr. Floyd E. Keene. He said that the substance used for injecting the kidney was collargol. It gained entrance to the kidneys by way of the tubules. The literature on the subject showed that pain was the most prominent symptom following the injection, but he believed that this was caused by faulty technique. He thought that collargol properly injected produced no widespread lesions of the kidneys. The indiscriminate use of pyelography was condemned. Pyelography was used only in those cases where it was impossible to make a diagnosis by any of the usual methods. In giving the injection the gravity method was employed, and the strength of the solution used was 10 per cent. All dangerous symptoms were prevented if care was exercised and the cases properly selected.

Dr. W. F. BRAASCH of Rochester, Minn., said that pyelography was a valuable method of diagnosing conditions of the urinary tract. In a series of 2000 cases no serious results were observed. He believed that the silver iodide injections recommended by Kelly were good. In giving these injections a syringe was used. He thought that the ideal method was not as yet known.

Dr. HENRY D. FURNISS of New York thought that an ideal injection was one which was non-irritating and non-toxic. To avoid traumatism in administering the injection, the use of a soft rubber catheter was advocated.

Dr. ARTHUR E. HERTZLER of Kansas City, Mo., said the toxicity of silver was just being realized. He believed silver was active in 1-10,000 solutions. Silver infiltrated the leucocytes and was carried to all parts of the body.

Personal Experience with Exclusion of the Pylorus in the Treatment of Ulcer.—Dr. WILLARD BARTLETT of St. Louis presented this paper. He detailed a number of original methods which were undertaken in order to completely shut out the pyloric region without cutting the organ entirely across and closing the two ends blind. The results were shown by roentgenograms which were taken during life as well as by roentgenograms which were taken after the stomach was removed from the body. Histological examinations were made of the stomach wall on both sides of the newly formed septum as well as of the septum itself. Physiological investigations were undertaken with a view of ascertaining secretory and motor functional differences on the two sides of the septum. He reported a series of twenty cases and was convinced that the unilateral closure was the most satisfactory.

Dr. WILLIAM L. RODMAN of Philadelphia said that many methods had been devised to exclude the pylorus. The methods were not adequate and gave only temporary relief. He believed Dr. Bartlett's operation

was ingenious. He had never used the exclusion method. He advised complete extirpation of the ulcer bearing area, since, in his opinion, the best way to prevent gastric cancer was to operate in the ulcer stage.

Common Errors in Gall-Tract Surgery.—Dr. C. E. RUTH of Des Moines read this paper. He said that lateral incisions in gall-tract surgery were never justifiable as they offered no real operative advantage and often led to serious complications. Through a median incision it was possible to do any gall-tract work which was possible through the lateral bayonet-shaped or any other lateral incision. The median incision was not followed by hernia and was readily extended for dealing with any complication within the abdomen. Drainage of the gall-bladder was never undertaken through the operation wound and the fundus of the gall-bladder was never attached to the abdominal wall. The pancreas was examined in every case.

Dr. EDWARD MARTIN of Philadelphia said that the median incision was valuable in the lean subject but was of no advantage in fat patients. He believed hernia rarely folowed operation in this region. He thought secondary operations were made necessary by the failure of the operator to make a correct diagnosis at the first operation. He approved of a lateral incision through the right rectus muscles, by which means the entire surface of the liver was exposed.

Dr. D. N. EISENDRATH of Chicago said secondary operations were performed in those cases where the gall-bladder was removed and where the common duct was not opened. He was not in favor of the median incision because through this method the entire liver region was not exposed. He opened the common duct first, and then worked upward to the gall-bladder.

Dr. JOHN A. MCGLINN of Philadelphia said secondary operations were performed on the gall-tract because the pathology of the affection was not understood. He believed that the trouble was not limited to the ducts and the gall-bladder, but that the upper right quadrant of the liver was also involved. He maintained that it was a surgical disease from the beginning, and was benefited only by surgery.

Thrombosis and Emboli: Their Significances and Consequences in Abdominal and Pelvic Surgery.—Dr. ANGUS MCLEAN of Chicago presented this paper. He said thrombosis and embolism played an important role in raising the mortality of modern surgery. Embolism and thrombosis followed septic cases more frequently than aseptic cases. Emboli were more frequently found in the spleen, kidneys, and brain. Portions of a diseased heart valve or parts of tumors were carried into the circulation and deposited as emboli. The conditions favorable to thrombosis were alterations in the blood current, changes in the vessel walls and in the blood itself. The treatment was mainly prophylactic. The danger of embolism from thrombosis usually ceased at the end of three weeks, as by that time the clot had become adherent to the vessel wall.

Standardization of Surgery: The Attack on the Problem.—Dr. ROBERT L. DICKINSON of Brooklyn read this paper. Pending the working out of a comprehensive plan, he outlined the progress already accomplished in the direction of standards and coordination and pointed out the way an individual surgeon or service was enabled to put into effect certain of the advanced methods adopted in the management of industries and developed by the studies of elementary motions and economy of effort. He said that the assistants in hospitals were not rated. There was no standard. Hospital superintendents were organizing. In Philadelphia fifty-five of the hospitals were organized. He advocated a study of details, the organization of a planning department, and constant inspection by one delegated to this duty.

The Pathological Physiology of Uterine Bleeding.—Dr. EMIL NOVAK of Baltimore read this paper. He said an intelligent study of the subject presupposed an understanding of the mechanism of normal menstruation. He referred to the fundamental importance of internal secretions, especially that of the ovary, which was the medium through which the entire ductless chain exerted effect on the menstrual apparatus. The effect was essentially of a vasomotor nature. He believed the causes of uterine bleeding were fundamental, as when caused by disturbances of the internal secretions: nervous, when produced by reflex disturbances, and, anatomical, when associated with structural changes in the pelvic organs or blood vessels.

Physiological and Pathological Variations of the Generative Organs Causing Atypical Bleeding.—Dr. JOHN G. CLARK of Philadelphia read this paper. He said that two organs were essential for the production of the menstrual flow—the ovary and the uterus. The ovary was the exciting and the uterus the active factor in this process. It was necessary to recast our views concerning a typical bleeding along newer pathological lines. New growths which were constructive in character followed the natural physiological periods of hemorrhage. Destructive new growths, such as cancer, deviated entirely from this law, and caused hemorrhage at any time. He urged that cancer of the uterus be diagnosed early.

Radium Treatment of Uterine Hemorrhage.—Dr. HOWARD A. KELLY of Baltimore read this paper, which was based upon a study of thirty-nine cases, covering a period of two and one-half years. He said that radium was a new and efficient means of controlling many cases of uterine hemorrhage. It acted well in small and medium-sized fibroids. It was also efficient in menarchial bleeding. The artificial menopause was readily induced with radium. Radium was a mild remedy, and when applicable, was better than surgery. The method of using the radium consisted in, first, dilating and curetting the uterus. Then, from 50 to 500 milligrams of the radium elements were introduced into the cavity of the uterus, together with a filtrate of 1 milligram of platinum and 3 milligrams of rubber, and permitted to remain three hours. Among the number of patients treated, twenty-one had fibroids. In two of the cases of fibroids the tumors completely disappeared after treatment with radium. There were no serious results following the treatment in any case. The treatment was successful in 90 per cent. of the cases. The cases were not selected. The radium treatment had an advantage over *x*-ray therapy in that it exerted its influence directly on the uterus.

Roentgen Therapy in Uterine Hemorrhage.—Dr. GEORGE E. PFAHLER of Philadelphia read this paper. He said that the cases most suitable for treatment were those in women approaching the menopause. The best results were obtained after the age of forty years. Under forty years, good results were obtained, but the patients required correspondingly more treatment. With accurate, massive, filtered doses of the rays, good results were obtained in a reasonable time, without danger and with no great inconvenience. In the series of cases reported, the use of the tampon was unnecessary after the first or second treatment. The object of the treatment was to regulate the function of the ovaries. The treatment also decreased the size of the fibroids. In fibroid cases, a gradual menopause was produced. The treatment was contraindicated in those cases of fibroids which had undergone malignant degeneration.

Dr. JOHN A. MCGLINN of Philadelphia said it was impossible to eliminate surgery entirely in the treatment of fibroids of the uterus. The mortality in these cases when treated surgically was due to cardiac or renal disease which existed in the patients. A study of the reports on treatment of this condition by radium and the röntgen ray showed that but 5 per cent. of the tumors disappeared.

Fundamental Intrapelvic Perineorrhaphy.—Dr. ALBERT GOLDSPOHN of Chicago read this paper. He stated that all classical perineorrhaphies were more cosmetic than curative. The only efficient structures with which to rebuild the female pelvic diaphragm were the levator ani muscle and its pelvic fascia. These did not extend anteriorly nearer to the former site of the hymen than from 4 to 5 cm. They were found within the pelvis and required an infravaginal and intrapelvic wound extending from 7 to 8 cm. inward posteriorly, and laterally from the junction of the mucous membrane and the skin. Some operations were too superficial and did not deal with the levator ani. Only deeply buried absorbable sutures extending in transverse loops without any intervening tissues were able to approximate the important structures so as to secure their stable union.

Pelvic Varicosities: A Definite Symptom-Complex.—Dr. WILLIAM EDGAR DARNALL of Atlantic City read this paper. He said he had operated on ten cases during the past year. Pelvic varicosities were caused by frequent abortions, excessive intraabdominal pressure, wearing tight clothing, etc. This class of patients complained of dull, boring pains in the lower abdomen. These pains were aggravated on standing erect, and were most pronounced at the menstrual period.

Many of these cases were incorrectly diagnosed as neurasthenia. The diagnosis was made by exclusion. Medical treatment was only palliative. Surgery offered a positive cure.

SECTION ON DISEASES OF CHILDREN.

Wednesday, June 24—Second Day.

Refractory or So-called "Fast" Cases of Meningococcus Meningitis.—Dr. H. HEIMAN of New York presented this paper. He said he had not used the old term epidemic cerebrospinal meningitis, which might be due to the pneumococcus or streptococcus. Since the introduction of Flexner's antimeningitis serum in 1906 mortality had decreased from 75 per cent. to 25 per cent. A small percentage of cases, however, did not respond to serum. The endotoxins might be so virulent as to make the action of serum impossible. Bactericidal substances were insufficient to counteract the organism. Perhaps a sufficiently strong serum to counteract this type could not be made. These refractory cases ran a prolonged course with a high septic temperature. They generally ended fatally but sometimes there was retarded recovery. These cases were due to special strains of the meningococcus which were "fast" to ordinary serum. They might not respond to any but serum prepared from those particular cultures. Cases of fifty-eight days' or 112 days' duration still showed meningococci. These strains must be specially cultured in the laboratory and serum prepared. Another source of failure was in the unskilled use of serum. The mortality statistics were lowest when based upon the reports of the most competent workers.

Dr. LOWENBERG of Philadelphia said he wondered where statistics came from. He had seen many cases in a congested part of Philadelphia, but had gotten no results from the serum treatment. He might perhaps be an unskilled user of serum or the cases might all be refractory. He did not get serum from the Rockefeller Institute but from a good manufacturing chemist.

Dr. H. D. CHAPIN of New York said he had not had success with the gravity method of introducing serum.

Dr. DENNET of New York said they had been obliged to use a syringe for injection. They had difficulty with the gravity method.

Dr. ZAHORSKY of St. Louis said too large doses should not be used on account of giving a severe protein intoxication which diminished the resistance of the child. Two or three injections should be given and the body then allowed to rest.

Dr. MORSE of Boston said the meningococcus was not a single organism but a class. The type of organism had evidently changed in Boston. It used to respond to Flexner's serum, but now did better with the State Board of Health serum.

Urinary Analysis in the Diagnosis and Treatment of Diseases of Infancy and Childhood.—Dr. R. G. FREEMAN of New York gave this paper. He said that ordinary office examinations of urine did not always furnish sufficient information. Procuring urine in infants, especially females, was difficult. They urinated small quantities often. In pyelitis several specimens were necessary. Examinations should include estimation for specific gravity, acidity, albumin, glucose, acetone, diacetic acid, indican, phthalein, and microscopical examination of sediment. Albumin, unless found with nephritis, would most likely disappear. In children acetone might be detected in the breath. Acidosis occurred with cyclic vomiting and was best treated with alkalines. It also occurred in intestinal intoxication, and sometimes was associated with urticaria. Intertrigo occurred with high acidity in the urine. Cases of pyelitis were often neglected. A few leucocytes in the male baby, and many in the female, were suspicious. It should be promptly treated. It occurred more often in females than males. It occurred very likely from contamination with feces. A child could be trained to have a regular movement of the bowel so that contamination did not occur. With a number of leucocytes present an examination for bacteria should be made, and if they were present they should be grown on culture media.

Dr. SEDGWICK of Minneapolis found that in recurrent vomiting there was increased creatinin and creatin excretion and casts. Acidosis occurred with the withdrawal of carbohydrates and care should be taken not to mistake acidosis for the fundamental condition. That more frequent infections in females must take place through the urethra was not proven.

Dr. LENNING of New Haven said it was important to collect several specimens.

Dr. HELMHOLZ of Chicago said he agreed with the last speaker. In chronic cases one might get no pus for several days and then a gush of pus. An orthostatic albuminuria should also be distinctly recognized.

Dr. BUTTERWORTH of New Orleans said that acidosis might be present in almost any febrile condition. He thought pyelitis frequent in males as well as in females.

Dr. HEIMAN of New York said that in orthostatic albuminuria the first specimen on getting out of bed was negative. On rising to an angle of 45° albumin was found present. This was due to venous pressure. In toxic albuminuria the first specimen was positive for albumin.

Amebic Dysentery in Children.—Dr. R. L. DEBUYS of New Orleans presented this paper. He said the incidence was rare in children as they were less exposed to etiological factors, but it was more common than was usually believed. In the Charity Hospital in New Orleans there were four cases to every 3,000. It was more prevalent in the male on account of greater exposure. The sources were water and green vegetables. Amebic dysentery should be distinguished from bacillary dysentery which was more acute and toxic. Diagnosis was not difficult, and warm, liquid stools must be used to detect ameba. The symptoms were pus and blood in the stools, fever, prostration, anorexia, dry skin, frequent movements of the bowels; the blood picture was one of secondary anemia. A large number of cases should be studied before conclusions could be drawn. Treatment consisted of ipecac in form of pills. Emetin seemed to be the best form of treatment and complete rest for the bowel and for the individual was essential.

Dr. T. S. SOUTHWORTH of New York said that this was a disease of warm climates, but in these days when so many of our products came from the Southern States we should be on the lookout for cases. Emetin was no doubt of great help in this disease.

Dr. H. D. CHAPIN of New York said that every year one or two cases came under his observation. More careful search should be made for the ameba.

Dr. AMESSE of Denver said he believed that children had more or less of an age immunity to this disease, as Chinamen had a race immunity to typhoid and the negro to yellow fever. Children also had an age immunity to yellow fever. In emetin we had a drug to conquer this tropical disease.

Dr. BUTTERWORTH of New Orleans cited the case of a soldier who escaped death from dysentery in the Philippines, came back and married. His wife and four of the children contracted amebic dysentery. There was direct evidence of infection. Emetin was no doubt the best curative agent.

The Use of a Series of Vaccines in the Prophylaxis and Treatment of an Epidemic of Pertussis.—Dr. A. F. HESS of New York read this paper, reporting an epidemic of whooping cough in the wards of a large infant asylum. This gave an excellent opportunity to try vaccines, either preventive or curative in this disease. Four types of vaccine were used—the Bordet-Gengou, a Parke-Davis Bordet-Gengou vaccine, a Board of Health Bordet-Gengou vaccine, and autogenous vaccines isolated from the asylum cases. The children were all under the same conditions of living, feeding, and fresh air, and the same organism probably infected all of them. Of 75 unvaccinated cases 59 developed pertussis. Of 144 vaccinated cases 21 had pertussis. This would show some preventive power of the vaccine. When prevention failed the children did not have the disease more mildly, thus disproving a curative effect. The exposure to infection was the same in vaccinated and non-vaccinated. The results were not as good as in typhoid vaccine but were certainly of considerable help.

Dr. ZAHORSKY of St. Louis said results were better in private practice. Children in institutions had a low power of immunization.

Dr. MCCLEAVE of Berkeley, Cal., said that he had vaccinated well children as well as sick ones in an epidemic. The method was of value and should be used. He intended to determine the duration of the immunity.

Dr. HAMILL of Philadelphia said that the subject of vaccines should be carefully approached. Results were difficult of interpretation. The treatment was sometimes detrimental and sometimes gave alarming results.

Dr. MEADE of Middletown, Ct., said they had used a mixed pertussis and pneumococcus vaccine with remarkably good results.

Dr. Reimer of New York said that the earlier the vaccines were started the better were the results obtained.

Dr. Heiman of New York said that in bronchitis due to *B. influenzæ* children had a pseudo-pertussis cough. The distinction must be carefully made.

Examination of the Chest in Children.—Dr. R. M. Smith of Boston read a paper on the importance of determination of the presence of tuberculosis in children. In addition to the physical examination and the von Pirquet test, the temperature and history were important. The matter could not be left there as the determination of tuberculosis was of first interest. It was also necessary to distinguish between the mere presence of tuberculosis and the active stages of the disease. Of 100 cases nine were in active stages. Night sweats with children were an unessential sign. Of ten with night sweats none had active tuberculosis. Of sixty-five children with tuberculosis two were above average weight. This was merely a question of the feeding. The *x*-ray had been shown to be of marked value in aiding diagnosis; of fifty-two whose *x*-ray plates showed lesions all had signs in the lungs by auscultation, but twenty-one did not show signs on physical examination. The *x*-ray was an aid but could not take the place of careful physical examination. In cases with enlargement of the bronchial glands 100 cases showed thickening, in the *x*-ray plates, and seventy of these had the d'Espine sign. It would seem as if the d'Espine sign meant enlarged bronchial glands. In forty-one of these cases the von Pirquet test was also positive. Enlarged glands, however, did not necessarily mean tuberculosis. One case came to autopsy which had acute bronchitis and acute endocarditis. With a positive von Pirquet test in sixty-two cases fifty-six had also signs in the lungs and seven had active tuberculosis. The active cases should be distinguished and cases with old scars should not be treated for active tuberculosis.

Dr. Heiman of New York said there should be a bronchoscopic examination. Repeated attacks of bronchitis enlarged the glands.

Dr. Freeman of New York said that in miliary tuberculosis often there were only occasional râles. In tuberculous meningitis where there was very little sign in the chest, the *x*-ray showed extensive lesions; here the von Pirquet test was often negative.

Dr. Hamill of Philadelphia said it was possible to develop dullness over the bronchial glands by shifting the position of the child and of the muscles. The *x*-ray was misleading, unless in expert hands. Technicians of the better type were few and good interpreters fewer.

Dr. McLanahan of Omaha said the *x*-ray was misleading and did not take the place of careful physical examination. This was one of the best papers he had heard.

Dr. Chapin of New York added his testimony to that of Dr. Hamill. He had frequently found the *x*-ray misleading. In some cases of obscure late pneumonias it was of use. They gave few physical signs; the *x*-ray proved them superficial rather than central.

Dr. Zahorsky of St. Louis asked upon what Dr. Smith based his diagnosis of active tuberculosis.

Dr. Smith of Boston said he made a diagnosis of tuberculosis on marked loss of weight, obvious signs of illness and a positive von Pirquet, except in miliary tuberculosis.

The Use of Boiled Milk in Infant Feeding.—Dr. R. H. Dennett of New York in this paper said that it was frequently necessary to boil infants' food. In no single instance had he seen digestive disturbance follow from use of boiled milk. In changing from boiled milk to raw milk the stools frequently had curds and children frequently had indigestion. The prolonged use of boiled milk did not necessarily cause rickets, anemia, or malnutrition, but it might cause constipation. With the use of orange juice boiled milk did not cause scurvy.

Experience with "Whey-Modified" Milk in Infant Feeding.—Dr. J. S. Leopold of New York presented this subject in which he discussed the difficulty of always procuring breast milk. He advocated Schloss' "whey-modified" milk, a new milk preparation for infants resembling human milk in its modification of salts. Infants did not do as well on cows' milk because the percentage of salts in the two milks was different. In Schloss's milk the percentage of proteins, sugar, salts, and fat was the nearest approach to human milk. A small amount of flour was sometimes added for infants under three months of age. Young infants did very well on this milk preparation and showed good development. In the bringing up of institutional infants, which was usually difficult, this mixture answered very well. Those suffering from malnutrition and from enteritis made considerable gain on this food. Sometimes it could be given in conjunction with breast milk with good results. Schloss's milk was not indicated after six months of age.

Dr. Neff of Kansas City said he doubted if the heating of milk had any relation to the production of scurvy. Brennerman reported curing a case of scurvy with the use of boiled milk.

Dr. Royster of Norfolk, Va., said he had never hesitated to boil milk nor had he seen bad results from its use. He frequently used orange juice with boiled milk. He believed that Schloss's milk was a great help for institution babies.

Dr. Lowenberg of Philadelphia said his results with boiled milk were in accordance with those of Dr. Dennett; there was a good effect on the stools from boiled milk.

Dr. Douglas of Detroit said that for 15 years he had educated his patients to use boiled milk. He did not pay attention to scurvy. It was easily removed.

Dr. G. D. Scott of New York said he believed there was a change produced in milk by boiling. The whey modification seemed to be akin to the wine-whey of 15 years ago. In regard to scurvy it was, he thought, due to a poor condition of the milk. It was often delayed in the dairy. Scurvy could not be cured in a few days.

Dr. Zahorsky of St. Louis said he did not believe Schloss's milk was superior to a good top-milk mixture.

Dr. Graves of New York said he had experience in watching older men in practice and had seen scurvy develop under the hands of competent men in four cases. There was no doubt as to the serious suffering of the infants. Pasteurized milk might have been the cause. Orange juice could always be given with boiled milk.

Dr. Morse of Boston said that boiling of milk made casein digestion easier. In regard to the etiology of scurvy, the only safe statement to make was that no one knew anything about it.

Experiments with Swine Fat in Infant Feeding.—Dr. J. Zahorsky of St. Louis presented this paper. He said that the American practitioner had always been partial to the use of fat, but many young infants could not digest cows' milk unless the fat was withdrawn. Many fats had been tried, as olive oil, butter fat, cod liver oil, but these results were not as good as those given by swine fat which resembled the fat in human milk. Pure lard might be used and had been used in his experiments. He had proved that lard might be safely used. In institutional infants the lard fed babies looked better than the other babies and always were chosen for adoption instead of the others. Sometimes the infant refused the bottle, sometimes there was regurgitation, but usually the stools were yellow and there was no digestive disturbance. A 3 per cent. proportion of fat was used and was well tolerated.

The Absorption of Fat from the Intestinal Tract of the Actively Tuberculous Child.—Dr. F. W. Schultz of Minneapolis presented this communication. The tuberculous child needed a diet rich in fat. It was desirable to have as large a deposit of fat as possible in the organism, under any feeding conditions. It was equally desirable not to have an excess of fluid in the tissues. The former seemed to increase and the latter to decrease resistance to tuberculous infection. Experiments showed that animals fed with carbohydrates were less resistant to tuberculous infection and those fed with fat rich diet were very resistant to tubercle bacilli. The importance of fat to the tuberculous child brought up the question of fat tolerance. In peritoneal tuberculosis the blocking of the lymphatic channels markedly diminished fat absorption. In scrofulous cases the fat absorption in the stools was found diminished. The conclusion was that a diet with most fat and causing least retention of water was the most favorable to tuberculous children.

Dr. Talbot of Boston said that the problem was a mechanical one and a question of how much fat could be absorbed.

The Influence of Starch on Infant Digestion.—Dr. T. S. Southworth of New York read this paper. He said he was not arguing for excessive starch feeding. The reason for giving the starch was to render curds permeable by the gastric juice. Vegetable proteins supplemented the animal proteins of the milk. The stomach was, however, only the receiving house. Absorption took place mainly in the intestine. Peristalsis churned the food and mixed it with the secretions.

Disturbances arose from fermentation or abnormal cleavage which irritated the mucosa and interfered with absorption. The addition of starch in some form to feedings mixtures was widespread. In hospitals the stock formulæ included barley water as a diluent. Boiled starch apparently exerted a protective action against fat and might act as a curative agent in intestinal indigestion. Starch seemed unnecessary before the seventh month, but young infants could digest a moderate amount of boiled starch.

The Metabolism of Carbohydrates with Special Reference to Its Effects on the Absorption of Fat and Nitrogen and on the Retention of Salts.—By Dr. F. B. Talbot and Lewis W. Hall of Boston. Dr. Talbot read the paper, a study of carbohydrate metabolism in a baby in which the lactose, fat, protein, and ash balance were determined. The baby was admitted to the Massachusetts General Hospital suffering from digestive disturbance. After admission it increased in weight; at five months it weighed 9 pounds. Fat and protein were kept the same in the feeding, sugar was increased in successive periods. The child had one attack of diarrhea and was put back to former formula. It then lost weight. It got 115 calories per kilo of body weight. The urine never contained sugar. With increased amounts of sugar there was increased retention of protein. With increase of fat there was also a change of retention. The increased amount of sugar had no effect upon the absorption of fat or protein; they remained normal. There was no effect upon the absorption of ash. With the diarrhea fat absorption dropped from 90 to 75 per cent. Absorption of nitrogen also dropped. The acidity of the stools increased with the diarrhea. It was not determined how much sugar was lost, but taking fat alone the baby lost in the stools 15 calories per kilo per day.

Dr. Douglas of Detroit said there was an excess of sugar in many patent foods. In some cases this caused injury to the baby.

Dr. Morse of Boston asked Dr. Talbot if they were justified in concluding that variations in the percentage of sugar had no influence on the absorption of fat and nitrogen; also how much of the loss during the diarrhea was chemical and how much mechanical.

Dr. Zahorsky of St. Louis said that some sugars fermented more easily than others. Cane sugar and milk sugar were not easily fermented.

Dr. St. Clair of Philadelphia said that starch was very valuable in digestive disturbances.

Dr. McLanahan of Omaha said the mothers often objected to the expense of cooking cereals. He would like to know of a readily prepared "cooked starch."

Dr. Helmholz of Chicago asked Dr. Talbot whether a great deal of sugar could not have been contained in the organism and with it water, which after the diarrhea so reduced the weight of the infant.

Dr. Southworth stated that rapid peristalsis interfered with the absorption of fat and nitrogen.

Thursday, June 25—Third Day.

Blood Pressure in Normal Children.—Drs. C. F. Judson of Philadelphia and Dr. P. Nicholson of Ardmore, Pa., presented this paper, which was read by Dr. Nicholson. They dwelt upon the importance and value of accurate blood pressure estimation in children. Physiological factors influencing blood pressure in children were the relative instability of equilibrium of the vessels; lesser peripheral resistance; variations of blood pressure with height and weight of child; the influence of sex; the pressure being higher in the male; and the time of taking pressure, the pressure being higher later in the day. Of different methods palpation was the oldest; this, however, gave no diastolic pressure. The oscillatory method was more reliable but nervousness in the child often interfered with results. The newer modified Erlanger apparatus gave the most satisfactory results and comparison with other methods confirmed the accuracy of this. Observations showed that the variations of blood pressure in children were greatest between 10 and 14 years; the systolic pressure increased from 3 to 10 years and varied from 91 at 3 years to 105 at 14 years. The diastolic pressure remained level and pulse pressure increased in proportion. The most important point was the determination of pulse pressure, indicating peripheral resistance.

A Study of the Blood Pressure in Anemia in Infancy.—Drs. J. L. Morse and E. T. Wyman of Boston presented this communication. They said there were very few data in the literature of blood pressure in infancy and nothing as to blood pressure in anemia in infancy. The comparison of normally nourished children and anemic children had been taken in respect to blood pressure. Tests had been made on the arm wherever possible, otherwise on the thigh. The systolic pressure was noted when the sound was first heard; the diastolic when the sound changed from sharp to dull. In 62 per cent. of normal babies the average pressure was 90 mm. diastolic. Pressure was higher in males, and higher in second year than the first. In poorly nourished babies the systolic pressure was the same, the diastolic lower and pulse pressure higher. The pulse pressure was higher according to the degree of anemia, or disturbance of nutrition. Systolic pressure rose with increase of anemia. These cases did not warrant conclusions as to their cause.

Dr. Michael of Chicago said, in making observations on blood pressure, she had calculated the areas per square mm. over which the pressure circulated, had multiplied the circumference of the arm by the width of the cuff and had divided the height of the mercurial column by this sum. With this method there was found to be little result at 5, 6, and 7 years of age. Blood pressure seemed about the same in normal children and age influenced it but little.

Dr. Hill of Philadelphia said he used a 6-inch cuff, doubled. He thought the pulse pressure had more bearing than the systolic pressure.

Dr. L. F. Bishop of New York said the diastolic pressure threw more light on many cases than the systolic pressure; it was a great help in diagnosing aortic regurgitation; with a low diastolic pressure more blood was regurgitated.

Dr. Ritter of Chicago said that the blood pressure varied considerably as the patient sat or stood, more so in health than in disease.

Dr. Hamill of Philadelphia said he had found auscultation unsatisfactory. His results in systolic pressure corresponded with the results quoted.

Dr. Judson of New York said that he thought Dr. Michael's method of dividing the area into the quotient added one more difficulty to the technique.

Dr. Nicholson said in conclusion that Dr. Ward Crampton's work on blood pressure variations with reference to the posture of school children had been carefully worked out. He himself had not had time to go into this question.

Prognosis and Diagnosis of Congenital Cardiac Disease.—Dr. Charles Hunter Dunn of Boston in this paper dealt with special studies undertaken in Vienna in an obstetrical division of a large hospital. The study covered about forty cases. The diagnosis of these cases was difficult clinically. The text-books were misleading in treatment of the subject. His conclusions were often made in spite of the literature. Many statements made by men of high authority were not found to be justified. Several lesions together were often confused with a single lesion. In the cases studied diagnosis was confirmed at autopsy in forty; eight additional cases were found where the physical examination gave no hint of cardiac lesion, and in four cases a diagnosis was made and the autopsy showed a normal heart. Cases included open foramen ovale; pulmonary stenosis; deficient ventricular septum; patent ductus arteriosus; congenital malformation of pulmonary artery. Open foramen ovale by itself had little clinical significance. Pulmonary stenosis was the sole lesion in sixteen cases; all these babies died under three weeks and were all blue babies. Where they survived this was not the sole lesion. In all forty cases a systolic murmur was present. Enlargement was found to be an essential sign in pulmonary stenosis. Open ductus arteriosus was found to be a help when combined with pulmonary stenosis and not a hindrance to the circulation of blood from the right heart to the left. In these cases a murmur was always found to be transmitted to the neck. A case of murmur without cyanosis or enlargement was always open ductus arteriosus alone.

Dr. Schultz of Minneapolis said that no doubt pulmonary stenosis occurred in a large number of cases.

Dr. Helmholz of Chicago said this paper would be of great help in distinguishing the different lesions.

Dr. Zahorsky said that transposition of the vessel had not been mentioned. That might produce cyanosis. Open foramen ovale was a safety valve in congenital cardiac disease.

Dr. Bishop of New York said that many cases of congenital heart lesions survived to a good age and could do good work. He knew a man of 56, the president of a railroad, who for years had had a blood pressure of 320, the effort of the heart to compensate.

Dr. ALLEN HOLYOKE said he knew of cases where there had been two or three blue babies in a family.

Dr. SEDGWICK of Minneapolis said that pathologists gave a false impression to students as to the importance of an open foramen ovale.

Dr. MORSE of Boston said he knew of a boy with a very pronounced heart murmur. The boy was 16 years of age and as he was a very quarrelsome boy he had been allowed to learn boxing. He had never had any untoward symptoms from this.

Further Observations Concerning the Relation of Heat to Infant Mortality.—Dr. H. F. HELMHOLZ of Chicago presented this paper. He emphasized the need of very complete details daily as to feeding of the child, the passages of the bowels, records as to maximal and minimal temperatures, records as to humidity, and variations between room and outdoor temperatures. Observations extended over two months in 1913 during severe heat. No definite relation of high room temperature to gastrointestinal disturbances had been recorded. Most rooms were often above 85°, some above 90°. A room temperature of 90° could occur without hyperthermia in a child. Infants showed a remarkable power of adjusting themselves to high temperature. Where deaths occurred in periods of greatest heat it was always found to be owing to carelessness or ignorance of the mother. It was found that if properly cool clothing was used and proper care that infants could withstand much higher temperatures than generally supposed.

Dr. ROYSTER of Norfolk, Va., said that proper attention had not been given to humidity. With proper radiation children could stand much higher temperatures. Liefmann and Lindemann had no knowledge of the question of humidity. In Berlin it was considered high at 45 per cent.; here it was rarely under 85 per cent.

Dr. LEVY of Newark said that the number of persons in a room and the air currents passing through the room would also determine heat and radiation.

Dr. SMITH of Boston said that Dr. Royster's point should be emphasized. Humidity was a very large factor. In his experience with the floating hospital, days of high humidity always brought a number of admissions of exhausted babies.

Dr. DOUGLAS of Detroit said parents should be taught to put very light and scanty clothing on the child in hot weather.

Dr. ZAHORSKY said he was not convinced that heat produced diarrhea. With a temperature of 100° in St. Louis he had seen no diarrhea. Atrophic infants with low resistance succumbed to a heat wave and this increased the death rate.

Dr. BUTTERWORTH of New Orleans said they lost more infants in April than in hot weather. Sudden rises and falls of temperature were trying to infants. The immature nervous system was unable to adapt itself to sudden changes.

Dr. BURTON of Albuquerque, Mexico, said that with them cases of indigestion were very few during the summer. There was great difference between day and night temperature. The children were kept in the shade in the daytime.

Dr. ILLOWAY of New York said that heat alone was not the cause of mortality. Summer heat had a depressing effect on the nervous system and caused lowered resistance.

Dr. ELIAS of Asheville said that at an elevation of 3,000 feet in Asheville there was a lack of atmospheric moisture, but with a dry summer the flies were usually bad and caused many cases of diarrhea; these were more frequent in the country than in town.

Dr. MCCLEAVE of Berkeley, Cal., said that 90° with them was not an excessive temperature. Temperatures were often above 110°. Heat of itself seemed to have no effect. They had no summer diarrhea even with temperatures of 115°.

A Further Clinical Study of the Efficiency of Sodium Chloride in the Therapeutics of Bright's Disease.—Dr. H. LOWENBURG of Philadelphia read this paper. His results dealt with definite biochemical phenomena and confirmed the observations of Fischer in which all cases were relieved by the use of sodium chloride. Dr. Lowenburg's original observations were made before Fischer's work. In his experience edema might or might not occur with nephritis. Hypodermoclysis with warm saline solution in wasted individuals who had been dehydrated was helpful and curative. In intestinal intoxication the effect of acidosis was a dissolution of the gelatinous colloidal substances of kidney tissue. This resulted in albuminuria. The presence of neutral salts dissolved the acid. Rabbits had been cured of experimental nephritis by injections of sodium chloride. A salt-free diet might lead to albuminuria and nephritis, due to low salt content of the body. He had been able to confirm clinically that the output of urine was increased by the use of neutral salt.

Dr. SOUTHWORTH of New York said that the use of sodium chloride was opposite to the teachings he had heard on the subject. He understood, however, that in a recent case of typhoid fever with nephritis the introduction of saline solution by rectum had been helpful.

Dr. ZAHORSKY of St. Louis asked whether the use of hypodermoclysis was preferable to drinking plain water after giving potassium acetate with sodium.

Dr. NICHOLSON of Ardmore, Pa., said that introduction of saline solution into the bowel was better than its administration by mouth. It was absorbed by the rectum.

The Use and Abuse of the Tonsils.—This paper was presented by Dr. J. H. COMROE of York, Pa. He said that the tonsils had been accused of causing many pathological conditions. Many tonsils, however, should be saved that were condemned without hearing. Statistics showed that there had been 37,000 recommendations to parents to have the tonsils of children removed, by school inspectors. This wholesale condemnation of the tonsils should be reconsidered. The organ had not been proved valueless. It was the first line of defense against microorganisms. Many bacteria were taken up by the phagocytic cells. A passage of leucocytes occurred from the tonsil to the buccal cavity. In the healthy person the tonsil contained many leucocytes. The current of lymph from the tonsil served to wash away infecting organisms, and lymphatics drained the crypts of the tonsil. The removal of the tonsil was not always a simple matter and many deaths had resulted from it. The tonsils served a physiological rather than a biological function and should not be carelessly eradicated.

Dr. ZAHORSKY of St. Louis said that often the tonsils served for the production of immunity. After the removal of tonsils very many cases showed frequent bronchitis and bronchopneumonia.

Dr. SOUTHWORTH condemned the wholesale slaughter of the tonsils. Half the cases of tonsils sent by medical inspectors for removal should be sent back. The tonsils no doubt acted protectively by means of an internal secretion.

The Relation of Bovine Tuberculosis to Early Tuberculosis in Childhood.—Dr. T. C. MCCLEAVE of Berkeley, Cal., stated that tuberculosis was in origin a disease of early life. To prevent early tuberculous infection was the fundamental problem. A large proportion of cases in infancy were derived from tuberculous cattle. The importance of this fact demanded investigation. The British Royal Commission and the German Commission had found that in children tuberculosis of the meninges and of the lymph glands was often bovine in origin. Frazier had found 73 per cent. of cases under three years of age who had been fed on raw cows' milk. Pulmonary tuberculosis might later be caused by the carrying of tubercle bacilli by the lymph glands and blood stream and become active after many years. A transmutation from bovine to human tuberculosis might thus occur. It might be asked what become of the cases of early tuberculosis if bovine bacilli did not change in the adult cases. The supervision of dairy cattle was of the highest importance in this respect. Every year's report of inspection of cattle showed 20-30 per cent. of tuberculous cows. This was a serious menace in view of the possible transmission of germs to the baby. In view of the present primitive hygiene obtaining in most dairy farms the practice of pasteurization in the home seemed to be the only safeguard and should be universally advocated.

Dr. H. L. COIT of Newark said the importance of medical supervision of the milk supply should be emphasized. The percentage of tuberculous cows had been greatly diminished, but even certified milk was not always entirely reliable.

Dr. RITTER of Chicago said that the glandular form of tuberculosis might be called a secondary form and that pulmonary tuberculosis might be classed as a tertiary form. We had no special data as to transmutation. All the acid-fast bacilli were interrelated, but one could not be changed into another. Koch contended that bovine bacilli would never produce pulmonary tuberculosis.

Dr. LEVY of Newark asked why children with gland-

ular tuberculosis did not develop pulmonary tuberculosis. Did they develop a sort of immunity?

Dr. SMITH of Boston said that this question should receive more attention than it did. The only course that was satisfactory was not to give milk raw.

Dr. HELMHOLZ of Chicago said that in spite of milk commissions you could not be sure of certified milk. It should not be given raw.

Dr. DOUGLAS of Detroit said that it was not safe to assume that any milk was safe. All milk should be boiled.

Thoracic Complications of Rickets.—Drs. J. HOWLAND and E. A. PARK of Baltimore presented this paper, which was read by Dr. Park. It dealt with a severe form of rickets which increased the danger from the disease. In this form the thorax was especially affected. The disease might be mistaken for osteomalacia. The thorax lost its rigidity and no longer withstood the atmospheric pressure and the pull of the diaphragm. In these cases the thorax was smaller than the head; the chest was shaped like a wedge, the anterior part of the chest being the narrow end. Many fractures of the ribs might occur. The deformity of the chest resulted in diminution of capacity and reduction of the volume of the lungs. The deformity was greater on the right side than the left, as the heart protected the left side. With inspiration the deformity was increased and there was an actual decrease in the circumference of the thorax. With such a crippled thorax respirations became very rapid, sometimes 80 to 100. Any pulmonary infection became very dangerous. The lung became emphysematous in front and atelectatic in the posterior lobes. The volume of both lungs was much reduced. The heart in these cases became hypertrophied in the right ventricle. The weight of the heart was increased, being the weight of a normal child's heart, while the child itself was much under weight. Death was due to failure of respiration by mechanical causes. The *x*-ray pictures of such cases were characteristic.

Dr. OSTHEIMER of Philadelphia asked whether the fractures occurred at one time or continued to occur later.

Dr. HOWLAND of Baltimore said this was a very severe kind of rickets; milder cases showed no such deformity. Rickets might run on for years with remissions, and fractures might occur with an exacerbation.

Dr. SOUTHWICK of New York said that while these severer cases caused death, in other cases rickets was a contributing cause. These children very often died of pneumonia.

Dr. MCKEE of Philadelphia said that this paper was a distinct contribution to our knowledge of rickets. Aside from the question of etiology our knowledge of rickets was a closed chapter.

Dr. PARK said in regard to fractures, cases of fragilitas ossium showed multiple fractures of the extremities as well as of the ribs. Osteoporosis caused fractures of the long bones, but the condition was different from osteogenesis imperfecta.

Fragilitas Ossium.—Dr. MAURICE OSTHEIMER of Philadelphia read this paper in which he gave a detailed report of a case of a female child, of three years, of Russian Jewish parentage; breast-fed for one year; no previous illness except pertussis. The parents said she fractured her leg whenever she tried to stand up; at three years she fractured the humerus. The musculature was good; the head showed protuberance of parietal bones; the neck was short; thorax pigeon breasted; reflexes normal; the blood showed 3 per cent. eosinophiles; Wassermann and von Pirquet negative. She was taken to the Philadelphia Hospital on account of a gonorrheal vaginitis. The parents took her away from the hospital, after which she often fractured her legs. When last seen she could walk a little, but her appearance was anemic. Up to the age of four she had had nine fractures. The literature of these cases showed 193 cases in all. The term fragilitas ossium was used to include the two types of the disease, both the fetal type and that found after birth with imperfect bone formation in which fractures occurred until puberty or even adult life. The cases did not include osteomyelitis due to syphilis or tuberculosis. In this disease the layers of the periosteum were thickened; the marrow contained much connective tissue; the formation of normal osteoblasts was checked; there was increased absorption of bone trabeculæ and the bones thus became porous and extremely fragile.

(*To be concluded.*)

PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Sixty-second Regular Meeting, Held April 3, 1914.

THE PRESIDENT, DR. JAMES, IN THE CHAIR.

Laboratory Aids in the Diagnosis of Acute Mastoid Disease.—Dr. BACON read this paper. (See page 1.)

Dr. DIXON said that he had begun the radiological studies of mastoid diseases with great misgivings because of the fact that there were no standard pictures of the mastoid process and from the nature of things could be none, as this structure varied in appearance in almost every individual, even the two processes in the same person being sometimes quite different. Of course the great distinction between the so-called pneumatic process, the cells of which are made up of large air spaces, and the sclerosed process was easily shown. Very fine differences had soon also been recognized in the pictures until he had gained confidence enough to be able to judge of the site and perhaps of the degree of inflammation from the pictures. At present Dr. Dixon had no hesitation in reporting upon the picture as indicating operative or non-operative condition in the great majority of cases. Of course, the first condition of such reports was the production of good pictures. He had succeeded by constant practice in producing pictures that showed the landmarks with fairly constant relation to each other. Very interesting were serial pictures or rather pictures taken at intervals. In several cases evidence from such pictures either confirmed the suspicion of operative condition or allayed the fear that suppuration was present. Dr. Dixon thought that it might be advisable to take a picture of the mastoid process after such infectious disease as scarlet fever or during any middle ear affection, so as to have a standard to judge by if any symptoms appeared at a later date. Dr. Dixon showed numerous plates to illustrate his remarks as well as some of the cases described by Dr. Bacon in his paper. Dr. Dixon thought that bacteriological examination of the discharge from the ear or of the pus obtained in mastoid operations was of great value, especially so far as prognosis was concerned. While mixed infection was frequently found in middle-ear material, still the predominating organism was fairly easily determined. Usually this organism was obtained in pure culture from the mastoid cells, the sigmoid sinus or from a brain abscess if this condition had developed. His experience showed that the infection most to be dreaded was that with *Streptococcus Capsulatus*. The initial symptoms in such cases were frequently very mild, but the tissues seemed to have very little resistance to the spread of the organism. Therefore if this organism was suspected or shown to be present, radical operations were in order.

Dr. MILLER said that he was glad to hear that bacteriological and *x*-ray studies might be counted upon to help clinical evidence in some conditions depending upon middle-ear disease and similar affections. He had lately observed a child that had showed some disquieting symptoms after a simple operation for adenoids. There seemed to be perfect recovery shortly after the operation, yet in the third week the child had become irritable and had developed some irregular fever. Of course middle ear infection was suspected, but there was very little evidence on examination. Finally the child showed some meningeal symptoms, yet lumbar punctures proved negative. When operation was finally performed abscess of the brain was discovered. The speaker was anxious to know how frequent was such almost total absence of symptoms as the infections progressed. To him this case had proved very disquieting indeed.

Dr. BACON thought that the case described might have belonged to those rare conditions where infection of the brain had taken place directly from the middle ear without the infection of any more closely related structures. He thought it of course probable that infection had occurred after the operation for adenoids, or rather that avenues for absorption of infective matter had been opened during the operation.

Dr. KNAPP said that he wondered whether an *x*-ray plate might not give some indication of the amount of drainage that might be expected to take place in an infected mastoid process and thus give some hint as to the prognosis to be expressed in any individual case.

Dr. BACON did not think that a plate could be ex-

pected to be useful in this direction. It would show the amount of air space and of solid bone, but it would give no indication of the drainage relations that existed or of any fine communications between the various cells. Dr. Bacon added that his paper attempted to show how useful both *x*-ray examinations and laboratory examinations have proved in the diagnosis and prognosis of mastoid disease. At the same time he would not like to leave the impression that these newer methods of examinations had superseded the earlier clinical evidence obtained from careful study and observations of the patients. The newer methods were to a great extent corroborative of the clinical findings and the results obtained by them should be looked upon in this light. At the same time there was occasionally a case where the evidence obtained by successive *x*-ray plates, for instance, might prove pathognomonic of some pathological state in the mastoid which was not giving sufficient clinical data at the time. Thus one of Dr. Dixon's cases showed the gradual and progressive development of an abscess in plates taken at several weeks' interval, and the operation performed largely on the strength of this evidence proved the correctness of the diagnosis made. Dr. Bacon said that various other plans had been devised of late to increase the exactness and the scope of clinical observation; thus a fairly useful mastoid transilluminator had been devised. As for himself he had been anxious for some time to make the judgment of tenderness on pressure on the mastoid more exact than had been possible when simple finger pressure was used. The latter must, of necessity differ in almost each instance it was applied, and, moreover, there was no way of recording the findings in a comparative way. He had therefore devised an instrument in which the pressure on the mastoid was applied by a fairly hard, ball-like instrument, the amount of pressure used being registered by means of a spring communicating with an indicator and scale. The instrument was still in a state of transition but had already proved itself very useful in the directions indicated.

Arteriosclerosis of the Pulmonary Arterial System with Dilatation of Pulmonary Artery and Hypertrophy and Dilatation of Heart.—Dr. L. A. CONNER showed this case. The patient, an Italian, male, aged 38, a cook, was admitted to the New York Hospital January 5, 1912. History of family and early life were negative. Had had typhoid ten years before admission. He was well thereafter until two years before admission when he had an attack of rheumatism (fever, fleeting involvement of joints, and sweats). Since this illness he had had palpitation much of the time. Had been able to work for two or three months then would have to go to bed with palpitation, dyspnea, and slight cough. During the past two years he had had five or six such attacks. He had used alcohol moderately. He denied all venereal disease. Physical examination showed a thin patient, of rather poor musculature, but skin and mucous membranes of good color. Head and neck were negative. Lungs showed good resonance throughout. Voice and breath sounds were apparently normal; there were a few râles at both bases behind. The liver extended from the fifth intercostal space to the costal margin. The spleen was normal. Abdomen was negative. Testicles were normal. Epitrochlear glands were slightly enlarged, other glands were of normal size. Reflexes were normal. Eye grounds were negative. Heart: the lungs were voluminous, making cardiac percussion very unsatisfactory. Relative dullness was made out from 3 c.m. to right to 9 c.m. to left of middle line. There was slight dullness in first and second intercostal spaces to left of sternum. Intercostal spaces were abnormally wide so that nipples were situated in third intercostal space. In the third intercostal space on the left side was a wide area of heaving impulse which seemed to correspond with broad cardiac apex. The point of maximum impulse was about 8 c.m. from midsternal line. Over the region of the apex immediately preceding the systolic impulse was seen a sudden quick lift which seemed to correspond to the systole. A systolic impulse was seen in the second intercostal space 6 c.m. to 8 c.m. to the left of the middle line. On palpation in the third left space there was a strong slow lifting systolic impulse and distinct shock at beginning of diastole. This diastole shock was felt even better in pulsating area in second space, to the left of the sternum. No cardiac impulse was felt behind the sternum; no thrill was felt anywhere. In the interspace over the region of the apex was heard a faint systolic sound which was followed by a faint systolic murmur, the latter in turn being followed by a very loud thumping second sound. Near the sternum in the third left space, and more distinctly in the second left space, a long diastolic murmur was heard immediately following the second sound. The direction of transmission of this diastolic murmur was downward along the left border of the sternum, rather than outward towards the apex. To the right of the sternum two very faint heart sounds were heard. Action, regular and slow. The arteries were thickened, the pulses were large and soft. Four weeks later apex beat was in the fourth intercostal space, rather nearer the sternum than on previous examination. The greatly accentuated second sound persisted in the second and third intercostal spaces with the loud diastolic murmur following. The first sound was prolonged and somewhat "interrupted," but there was no distinct systolic murmur. On admission his blood pressure readings were: Systolic, 105; diastolic, 85. Two weeks later systolic pressure in right arm was 115; diastolic pressure 85. Blood culture was negative after four days incubation. Wassermann reaction was faintly anticomplementary and apparently negative. Urine showed a faint trace of albumin and a few hyaline casts. The patient having been well aside from two short attacks of palpitation was permitted to go home February 9. Patient worked one and one-half days after leaving hospital, but the development of a severe dyspnea compelled him to stop work and go to bed. There was no edema, cough, or pain. On February 17 he was readmitted to the hospital. At this time he was cyanotic, lips and fingers being very blue, and he suffered from marked dyspnea. Heart sounds were full and clear, but an hour later rate became very rapid and sounds became embryonic in type. Gradually the heart action became slower and stronger and the physical signs then resembled those already described. Two days later patient complained of pain in the first and second intercostal spaces near sternum on coughing. On this day during an attack of coughing he became very cyanotic and dyspneic. Heart became very rapid and pulse imperceptible at the wrist. This condition improved after phlebotomy and the next day his general condition was better but heart action was weak. Three days later following a similar attack of cyanosis accompanied by a chill and temperature of 160° the patient died. For the last four days of life his temperature ranged between 103° and 106°. Leucocytes varied between 18,000 and 25,000. Differential count showed 75 per cent. polynuclear and 25 per cent. mononuclear. Blood culture remained sterile after four days' incubation. Autopsy performed by Dr. R. G. Stillman showed no scars or enlarged glands. The anterior borders of the tibiæ were normal. The diaphragm was situated at the level of the third rib on the right side and third interspace on the left. Spleen measured 17 cm. x 11 cm. Kidneys showed no gross abnormalities. Tongue showed no smooth atrophy. Heart and blood vessels: Heart was large, measuring 15 cm. in its longest diameter. The greater portion was made up of right ventricle. The tricuspid orifice admitted four fingers, the mitral orifice 2.5 fingers. The right auricle was very much enlarged, measuring 10 cm. in its longest dimension. The right ventricle was hypertrophied and dilated, the cavity being about three times its normal size and the wall being from 5 cm. to 21 cm. in thickness. The pectinate and papillary muscles were enormously hypertrophied, some of the latter being 6 mm. in diameter. The segments of the tricuspid valve appeared normal. The aorta presented a number of small irregular sclerotic patches equally distributed from its origin to the iliac arteries. Aortic valves were normal. The pulmonary artery was markedly dilated, measuring 8 cm. in circumference, 3 cm. above the point of origin. The right branch measured 6.7 cm. at the bifurcation and for 4.5 cm. beyond. The wall of the pulmonary artery was almost as thick as that of the aorta. One cm. from pulmonary valves there were present several small plaques of arteriosclerosis forming a ring around the vessel. One cm. beyond this the intima was wrinkled longitudinally and was atrophic in appearance, showing many plaques of arteriosclerosis varying in size from 2 mm. to 15 mm., occurring at irregular intervals. These plaques persisted into smaller subdivisions of artery, the wrinkled appearance, however, disappearing when vessels reached 4 mm. in diameter. The pulmonary valves were normal. Because of the systolic pulsation over the pulmonic area, the enormous accentuation of the second sound, the hypertrophy and dila-

tation of the right ventricle and the direction of propagation of the diastolic murmur it was evident during life that there must be marked obstructions somewhere in the pulmonary circulation which had caused dilatation of the pulmonary artery and a relative insufficiency of the pulmonic valves. The nature of the obstruction, however, was not suspected.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

PENNSYLVANIA STATE BOARD OF MEDICAL EXAMINERS.
December 2, 3, *and* 4, 1913.

(*Concluded from Vol.* 85, *p.* 1104.)

GYNECOLOGY AND OBSTETRICS, PHYSIOLOGICAL CHEMISTRY.

1. Given a pregnant woman, of seven months or more, stricken suddenly with severe hemorrhage, what would be your deductions? Outline the management of the case.

2. State pelvic measurements or other conditions that would warrant an interference with the natural progress of gestation or of labor: what procedure would you recommend in each condition noted?

3. Enumerate the conditions that must be considered in excessive or protracted bleeding in a non-pregnant woman: outline surgical operations or methods that may be required, with the reason for selecting each. (Omit details of operation.)

4. If at the third month, a primipara should engage you to care for her through the period of gestation and labor, give in detail your care of the case, including measurements and tests.

5. What injuries may result to the birth canal from labor? Give in detail the management of a case of normal labor, with a view of preventing such injuries.

6. What is the significance of sudden collapse and shock that might develop during labor? Outline your treatment for such a case. (Omit description of operation.)

7. What breast complications may follow confinement? Outline the care of the breast that would probably prevent such complications. If they should occur, how would you treat them?

8. Indicate the steps in the digestion and absorption of the food substances present in a ham sandwich.

9. Discuss the chemistry of intestinal fermentation and putrefaction.

10. How may blood be detected in the feces, and what is the significance of this finding?

SURGERY AND ANATOMY.

1. Enumerate the constitutional and local conditions that may cause delayed or non-union of bone after a fracture: State two surgical procedures for its correction.

2. Outline the methods of examination by which you would determine the existence of a fracture at the surgical neck of the humerus: what is the usual deformity in this fracture? What is the anatomical explanation?

3. Enumerate the early symptoms that are caused by a typhoid perforation. Outline a surgical operation for the same.

4. State the usual anatomical avenues by which infection reaches the mastoid process. Outline a surgical operation for mastoid abscess.

5. What anatomical structures may be involved in the extension of a bunion? Describe its surgical treatment.

6. Name the varieties of club-foot: outline a surgical operation for the correction of any one form, with the anatomical and mechanical reasons for employment of same.

7. In fracture of both bones at the forearm, the actions of what muscles should be specially considered? What character of splints should be applied?

8. Enumerate symptoms and conditions upon which might be based the diagnosis of a malignant growth of the breast: outline a suitable surgical operation, giving the surgical anatomy of parts.

9. What is the usual position of the fragments in fracture of the patella? what is the anatomical explanation? State, without details of technique, two methods of treatment.

10. Outline two methods of treating carbuncle—give reasons for employment of each.

PRACTICE AND MATERIA MEDICA AND THERAPEUTICS, HYGIENE, AND PREVENTIVE MEDICINE.

1. State the sanitary precautions to be observed in the treatment of scarlatina. What are its possible dangers? Give indications of three remedies that might be used in its treatment.

2. (*a*) Describe the technique of general anesthesia. (*b*) Give reasons for the choice of each one of three agents used for this purpose.

3. Give the management and treatment of a well-developed case of follicular tonsillitis.

4. Outline the most important factors in the treatment of a case of incipient tuberculosis.

5. Outline the therapeutic action of (*a*) santonin (cina, Homeopathic), (*b*) camphor, (*c*) cimicifuga, (*d*) aconite, (*e*) ergot.

6. Outline the general medical treatment in exophthalmic goiter. What symptoms, in your opinion, would indicate the need of surgical intervention?

7. Given a case of typhoid fever with hemorrhage, outline the management during the first period of the hemorrhage and post-hemorrhagic stage and state the therapeutic action of each drug used.

8. In the treatment of chronic interstitial nephritis, what dietetic and hygienic suggestions would you make? Name three drugs that might be employed in the treatment of this condition, with the precise reason for the employment of each.

9. What are the main objects accomplished by the scientific ventilation of a school building? What degree of temperature is most conducive to health and mental activity in such buildings.

10. What are the main dangers to be apprehended in raw milk as ordinarily found in the market?

ANSWERS.

GYNECOLOGY AND OBSTETRICS, PHYSIOLOGICAL CHEMISTRY.

1. *Severe ante partum hemorrhage* is most likely to be due to (1) accidental hemorrhage, due to premature separation of the placenta; (2) to placenta prævia.

The treatment is practically the same in each case, namely, to check the hemorrhage and promote delivery. In *accidental hemorrhage* the membranes should be ruptured and the vagina packed, or *accouchement forcé* performed; vaginal cesarean section has been employed. In *placenta prævia:* (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation turn the child and make the breech engage in the os; or, if the head presents forceps may be used if speedy delivery is necessary. The strength of the woman is then the main point to be cared for, and if in a reasonable time the uterus seems to be incompetent, the child may be delivered by art. In some cases of central placenta prævia, where rapid delivery is required, cesarean section may give good results for mother and child."

2. The following table (from King's *Obstetrics*) is a useful summary of the various indications:

WHEN CONJUGATE DIAMETER OF BRIM MEASURES	THE MODE OF DELIVERY AT TERM IS
Between 4 and 3½ inches.	By forceps.
Between 3½ and 2¾ inches.	By forceps, version, symphyseotomy, cesarean section, or craniotomy.
Between 2¾ and 2 inches.	Cesarean section, if child alive. Craniotomy, if child dead.
At 2 inches or less.	Cesarean section always. Craniotomy excluded, whether child dead or alive.

"As a matter of course, selection of the method of delivery must not depend solely upon the length of the conjugate diameter. Since we cannot during labor measure the pelvis exactly, and still less the child's head, the impossibility of mathematical rules for practice is painfully evident. Furthermore, no two sets of cases are exactly alike, and the experience of no two practitioners exactly similar; hence hardly any two authorities exactly agree with regard to the pelvic measurements determining the kind of operation to be

employed. In cases with the larger figures above mentioned, the operation called for will be comparatively easy; with the smaller measurements, more difficult. Among the host of other considerations upon which our selection must, in part, depend, may be mentioned: 1. The kind of contraction; whether (*a*) simple anteroposterior flattening, or (*b*) general contraction, or (*c*) both of these combined. 2. The site of contraction, whether at brim, cavity, or outlet. 3. The estimated size of the head and its degree of ossification. 4. Whether or not it be "arrested," or "impacted" (and at what point in the pelvis), or have passed through the os uteri. 5. The amount of dilatation of the os and the state of the membranes. 6. Retraction of uterus above the head with consequent vertical tension of vaginal wall. 7. Is the child dead or alive, and if the latter, will its life be jeopardized or lost by the proposed operation? 8. History of former labors (if any) and results of methods then employed. 9. The number of previous deliveries, as indicating present labor-power. 10. Imminent danger or actual occurrence of uterine rupture. 11. General condition of woman as regards her ability to survive the proposed operation. 12. The "presentation" and "position" of the child. 13. The existence of complications, such as hemorrhage, eclampsia, placenta prævia, prolapsed funis, etc. 14. The estimated knowledge, acquired skill, and native dexterity of the operator, together with (what is not often sufficiently considered) the kind of hand he happens to possess, whether small, soft, and pliable, or the reverse."—(King's *Obstetrics.*)

3. Excessive or protracted bleeding in a non-pregnant woman might suggest tumors (such as cancer and fibroma), menorrhagia, metrorrhagia infections, and displacements. The first procedure is to find the cause; fibroids require removal, or even a hysterectomy; cancer, if not too far advanced and if operable, needs a complete hysterectomy. Displacements require proper placing of the offending organs, such as hystereopexy or other suitable operation. Menorrhagia and metrorrhagia are often amenable to systemic or local treatment.

4. A primipara should be instructed fully in the hygiene of pregnancy, by which is meant the care which should be observed by the pregnant woman for the preservation of health and strength both of herself and of the fetus. The pregnant woman should take moderate exercise in the open air; in the last month massage may take the place of exercise. Daily bathing in tepid water, care of the teeth, regularity of the bowels, ample sleep in a well-ventilated room, plenty (but not too much) of simple, nourishing and easily digested food, at regular hours, clothing not too tight, especially about the abdomen and breast; attention to the nipples, regular examination of the urine, and the restriction of marital relations are the main points to which advice should be directed. In addition certain measurements are necessary; a pelvimeter will be required to make these measurements. The interspinal and intercristal diameters are measured, also the distance between the ischial tuberosities and the anteroposterior diameter, as well as the external conjugate. It is well to notice if the subpubic arch is narrowed; the diagonal conjugate is also estimated; from the latter the true conjugate can be obtained.

5. *Injuries which may result to the birth canal from labor* are: Lacerations of the cervix, vagina, and perineum, and (more rarely) rupture or inversion of the uterus.

Management of normal labor. During the first stage a rectal enema of soapsuds with turpentine (5 1) should be given, and when the os is dilated to the size of a silver dollar the patient should be placed in bed, lying upon the side toward which the fetal back looks. If the pain is severe, chloral hydrate (gr. 15) may be given every half hour for 3 doses.

During the second stage, examination should be made when necessary. In multiparas, the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pain; by restraining voluntary expulsive efforts during the pains, and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.

6. Sudden collapse and shock during labor may be due to severe injury, such as rupture of the uterus, severe hemorrhage (external or internal); "the strain of labor in a weak woman, some of the accidents of parturition, or even forcible attempts to expel the placenta, may occasion shock after delivery. Cases of this sort have been reported from compression of the left ovary in attempts to expel the placenta by Credé's method, the womb being turned upon the cervix so that the left side looks forward, and the ovary is grasped between the thumb and the uterine wall, when the hand is placed on the fundus of the womb in the effort of expression."—(Hirst.) Treatment consists of heat applied externally, stimulation by hypodermic, sub-mammary infusion of saline solution, checking hemorrhage or removing other cause; laparotomy will be required in case of rupture of the uterus.

7. *Diseases of the breast liable to occur during the puerperium* are: Engorgement, inflammation, abscess, and cracked nipple. *Engorgement* is treated by giving the patient salines, limiting the amount of fluid ingested, and compressing the breasts with a binder. *Inflammation* is treated by resting the part; supporting it, applying a hot boracic acid fomentation; nursing from the affected breast should be stopped at once. *Abscess* is treated by making an incision radiating from the nipple, and drainage, thorough antiseptic and aseptic precautions must be observed; the breast should be put at rest for a couple of days; saline cathartics may be necessary; also supportive measures. *Cracked nipples* require to be kept clean and dry; they may be protected by a nipple shield while the infant is nursing; an application of tannic acid or nitrate of silver may be used.

Prophylactic measures consist in not touching the breasts (by doctor or nurse or patient) without thoroughly clean hands; by washing and drying the nipple before and after nursing, and by proper attention to hygienic conditions before labor, and the nipple and breasts being preserved from pressure.

8. A *ham sandwich* may be supposed to consist of ham, bread, and butter. Ham consists of protein, water, and fat; bread consists of carbohydrate and water, with a little protein and fat; butter consists of fat, with a little water. The proteins are digested in the stomach by the pepsin of the gastric juice, and in the small intestine by the trypsin of the pancreatic juice. The fat is digested in the small intestine by the steapsin of the pancreatic juice, and by the bile; the carbohydrate is digested slightly in the mouth by the ptyalin of the saliva, but mainly in the small intestine by the amylopsin of the pancreatic juice. The products of digestion find their way into the blood by two routes: (1) By the blood-vessels of the gastrointestinal tract, which unite to form the portal vein, and (2) by the lymph vessels of the small intestine, which converge to empty into the thoracic duct. The water, inorganic salts, proteids, and sugar go by way of the portal vein to the ascending vena cava; the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular veins. The *process by which it is accomplished* is partly physical (osmosis and filtration), and is also due in part to selective action.

9. "Owing to the favorable conditions in the intestine for fermentative and putrefactive processes—*e.g.* heat, moisture, oxygen, and the presence of various microorgansims—the food, when consumed in excessive quantity or when acted on by defective secretions, undergoes a series of decomposition changes which are attended by the production of gases and various chemical compounds. Dextrose and maltose are partially reduced to lactic acid; this to butyric acid, carbon dioxide and hydrogen. Fats are reduced to glycerol and fatty acids, the glycerol, according to the organisms present, yields succinic acid, carbon dioxide, and hydrogen. The proteids under the prolonged action of the pancreatic juice are decomposed, with the production of leucin and tyrosin. These crystalline compounds are in turn reduced to simpler forms. The former yields valerianic acid, ammonia, and carbon dioxide; the latter gives rise to indol, which is the antecedent of indican, found in the urine. Skatol, another derivative of the proteid

molecule, due to bacterial action, gives the characteristic odor to the feces."—Brubaker's *Physiology.*)

10. *Chemical examination of the feces for blood.* "The detection of traces of blood in the feces from 'occult bleeding' from gastric or intestinal ulcers is often a matter of importance. For two days before carrying out the test the diet must be free from meat, or any other constituent which may contain hemoglobin. The test is then carried out as follows: A portion of the feces about the size of a walnut is rubbed up with 5 c.c. of water, if the stool is liquid it should be well stirred up and 5 c.c. measured out. The 5 c.c. so obtained is placed in a dry test-tube, and one-third of its volume of glacial acetic acid added; the tube is then closed with a rubber stopper and well shaken. Next pour on 6 to 8 c.c. of ether and invert the tube slowly several times, then let the ether rise to the top and pour it off in two portions. To one add ten drops of fresh tincture of guaiacum and twenty of ozonic ether or old oil of turpentine. A blue color shows that blood was present. To the other add a few drops of freshly prepared tincture of aloin and some ozonic ether or turpentine as before. A red color indicates blood. The tinctures used must be fresh. The guaiac tincture is made by adding a knife point of guaiacum resin to 3 c.c. of absolute alcohol; the aloin tincture by adding a similar quantity of aloin to 3 c.c. of 60-70 per cent. alcohol. The aloin tincture should have a yellow color." —(Hutchinson and Rainy's *Clinical Methods.*)

SURGERY AND ANATOMY.

1. *Delayed union, or non-union, in fracture is caused by:* Ill health, want of approximation of the end of the bone, want of blood supply in the bone, defective innervation of the bone, disease of the bone, lack of rest, and immobility.

Treatment: "When delayed union exists, seek and remove cause, treating constitutionally if required, and thoroughly immobilizing the parts by plaster. Orthopedic splints may be of value. Use of the limb while splinted, percussion over the fracture, and rubbing the fragments together, thus in each case producing irritation, have all been recommended. Blistering the skin with iodine or firing it has been employed. If the case be very long delayed, forcibly separate the fragments and put up in plaster as a fresh break. If these means fail, irritate by subcutaneous drilling or scraping, or, better, by laying open the parts and then drilling and scraping at many places."—(Da Costa.)

2. In fracture of the surgical neck of the humerus, there can generally be obtained a history of direct violence; a depression will be seen below the shoulder, the outline of the latter being normal. A well-marked crepitus can generally be obtained on rotation: the limb is shortened; the upper end of the lower fragment may be felt in the axilla. The upper fragment is adducted and rotated outwards by the short rotator muscles; the lower fragment is drawn upwards by the biceps, triceps, deltoid, and coracobrachialis; the lower fragment is also drawn inward by the pectoralis major, teres major, and latissimus dorsi.

3. PERFORATION OF TYPHOID ULCER. *Symptoms:* "When perforation occurs, violent pain develops. As a rule, there are tenderness, rapid pulse, costal respiration, abdominal rigidity, vomiting, and shock. Usually there is temporary reaction from shock, the subnormal temperature giving way to a normal or to an elevated temperature. The vomiting in some cases becomes stercoraceous. There is constipation and sometimes dullness on percussing the flanks. The face is Hippocratic. The patient may die of the preliminary shock or may react and die subsequently of blood-poisoning." *Treatment:* "Death is practically certain without operation. Operation should be done at once, proper means being adopted to combat shock. In many cases a general anesthetic should not be given, but a local anesthetic should be employed. The incision should be made in the right iliac region and the colon should be first located and then the end of the ileum. By locating the colon we obtain a fixed point from which to begin our search for perforations, and by opening the abdomen in the right iliac region we come down at once onto the perforated gut in the vast majority of cases. When a perforation is found, it should be inverted with two layers of Halsted sutures. It is not wise to excise the ulcer. If the bowel is very badly damaged, resection can be considered, but it is usually wiser to make a temporary artificial anus. After finding a perforation and closing it, examine to see if there are others. Close every perforation, and if a point is found where the thinning of the bowel-wall indicates that perforation is liable to occur, protect this point by inverting the area of ulceration by sutures. Clean the peritoneum by flushing with hot salt solution. Leave the wound open, insert strands of iodoform gauze and establish tubular suprapubic drainage. Elevate the patient a little in bed and employ continuous proctoclysis of salt solution." (Da Costa's *Surgery.*)

4. Infection generally reaches the mastoid process from the middle ear, spreading by way of the attic and antrum; it can also be carried through the circulation. *Surgical operation* for mastoid abscess is by an incision in the long axis of the mastoid, and opening of the mastoid antrum within the limit of Macewen's suprameatal triangle; by opening in this triangle there is no chance of wounding the lateral sinus.

5. Bunion is enlargement of the bursa over the metatarsophalangeal joint of the great toe. This joint can become involved, if the bunion extends. The treatment consists in resection of the joint to cure the deformity and also the bunion.

6. *Varieties of club-foot:* (1) *Talipes varus*, in which the inner edge of the foot is drawn up, the anterior two-thirds is twisted inwards, and the outer edge rests on the ground. (2) *Talipes valgus*, in which the outer edge of the foot is drawn upwards, and the inner side of the foot and ankle rest on the ground. This condition is the reverse of *talipes varus.* (3) *Talipes equinus*, in which the heel is raised and cannot be brought to the ground, and the patient walks on the toes and on the distal ends of the metatarsal bones. (4) *Talipes calcaneus*, in which the toes are raised and the heel depressed, so that the patient walks on the latter. This condition is the reverse of *talipes equinus.* Combinations of these also occur, and *talipes equino-varus* in which the heel is drawn up and the anterior half of the foot is drawn inwards and also inverted; the inner border of the foot is shortened; secondary contraction of plantar fascia, ligaments and muscles may follow. *Talipes equino-varus* may be treated in the early stages by fixing the foot in good position by a series of plaster-of-Paris casings, or by using a malleable metal splint. Tenotomy of tendons which hinder reduction in some cases is necessary, with the subsequent application of plasters. If the ligaments on the inner side of the ankle hinder reduction, they should be divided. In the neglected cases, where the patient has been walking on the outer side of the foot, *tarsectomy* is necessary. A wedge of bone, with its base outwards, is removed by a chisel or saw, irrespective of the joints, from the tarsus in front of the peroneal groove on the cuboid. The foot can then be brought into good position, and maintained so by plaster of Paris. (*Aids to Surgery.*)

7. In fracture of both bones of the forearm, the action of the following muscles must be specially considered: Biceps, brachialis anticus, pronator radii teres, pronator quadratus, and the long flexor and extensor muscles of the forearm. The splint should be inflexible, wider than the limb, and long enough to include the hand.

8. The presence of a tumor, dimpling of the skin, retraction of the nipple, with cachexia, enlarged lymphatic glands in axilla or above or below the clavicle, and microscopical examination of an excised piece of the tumor all aid in the diagnosis of malignant growth of the breast. *Treatment* should be early and thorough. However small the tumor may be, the entire breast and its corresponding lymphatic area, as high as the apex of the axilla, should be removed; for, once infection of the lymphatic spaces has occurred, the whole lymphatic area must be looked upon as infected. Successful operations depend upon a knowledge of the *lymphatics* and *extent* of the breast. The lymphatics begin in plexuses around the acini, which converge to vessels running along with the ducts and end in a subareolar plexus. From this three or four main lymphatic trunks run to the axillary glands. In addition, lymphatics run along the suspensory ligaments to the skin all over the prominence of the breast from the interacinous plexuses. Also vessels leave the deep part of the breast to join lymphatic plexuses in the pectoral fascia. The plexuses in the fascia run to the axilla, and also communicate with those in the pectoralis major. Lymphatic vessels pass into the mediastinum, and also communicate with those of the opposite breast and axilla. The extent of the breast is much greater than the prominence would lead one to believe. It extends

almost to the clavicle, just to the edge of the sternum, down to the seventh rib, and out to the mid-axillary line. The points, then, in operating are that the whole breast, the skin over the prominence, the pectoralis major muscle (except the clavicular portion), the fat, fascia, lymphatic vessels and glands of the axilla, must be removed, and in one piece, for if cut across at any part there is danger of strewing cancer cells on the wound and so infecting it with growth. Removal or division of the pectoralis minor facilitates the cleaning of the axilla. (*Aids to Surgery.*)

9. In fracture of the patella the fragments are generally widely separated; the lower fragment remains in place, being held by the ligamentum patellæ; the upper fragment is drawn up by the quadriceps extensor muscle. *Treatment* consists in: (1) The subcutaneous method, in which a wire is passed above and below the patella, and twisted. (2) Extending the leg on the thigh, applying a long posterior splint, and with bandages and adhesive plaster or Malgaigne's hooks keeping the fragments in apposition.

10. *Two methods of treating carbuncle:* (1) Two free incisions are made through the sloughing mass, at right angles to each other. This should only be done on young and robust patients, as the hemorrhage is profuse. (2) The slough is thoroughly scraped away, carbolic acid is applied to the surface, and antiseptic dressings are applied. Supportive treatment is always indicated.

PRACTICE AND MATERIA MEDICA AND THERAPEUTICS, HYGIENE, AND PREVENTIVE MEDICINE.

1. In *scarlatina*, the patient should be isolated, and not allowed to mingle with other people until the disease is over, and there is no discharge from eyes or nose. All toys, fomites, etc., must be burnt. The rooms occupied by the patient must be thoroughly disinfected. The doctor, nurse, and attendant must take care not to spread the contagion. *Dangers* are: Ear troubles, nephritis, bronchopneumonia, endocarditis, pericarditis, arthritis. *Three remedies*: (1) Sponging or baths to reduce the fever; (2) inunction with some oily antiseptic, to prevent dissemination of the desquamated epithelium: (3) Dobell's solution, or some similar preparation as an antiseptic wash for nose, throat, and mouth.

2. The technique of general anesthesia differs with the anesthetic used. In every case the patient should be examined and prepared beforehand. The details of administration may be found in every text-book. As a rule, ether should be used; chloroform is particularly available in labor; and nitrous oxide is of great use in brief operations, and where complete muscular relaxation is not necessary.

3. In follicular tonsillitis the patient should be in bed; calomel (followed by a saline) should be given to open his bowels; sodium salicylate, gr. x-xv, q. 3 h. may be given; hot fomentations externally are of service; potassium chlorate may be used as a gargle or sucked, in the form of tablets. Antiseptic sprays have been used; if an abscess forms it should be opened. Tonics, and nourishing food are indicated during convalescence.

4. *Incipient tuberculosis* demands outdoor life as far as possible, fresh air, well ventilated rooms; avoidance of fatigue; a daily sponge bath followed by rubbing; sun bath if possible; passive exercise; nutritious food with as much fat as can be assimilated, milk, eggs, etc.; extra meals, so that there is no long interval between meals; if possible, the patient should live in a suitable climate. The chief medicinal agents are cod liver oil, iron, creosote, strychnine, and arsenic. Tuberculin has been recommended, but it requires care and skill in its administration.

5. *Santonin* is a vermifuge for round worms. *Camphor* is an anodyne; is used in flatulence, diarrhea, hysteria, delirium tremens, for night sweats of phthisis, coryza, and bronchitis. *Cimicifuga* is said to be a stimulant; it has been used in cases of chorea. *Aconite* is used for fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritis, herpes, chilblains, etc. *Ergot* is used to promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headache, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

6. *Exophthalmic goiter* requires rest, both physical and mental; plenty of fresh air, and nutritious but easily digested food; applications of ice, digitalis, belladonna, bromides, iodides, iodine, electricity, and thyroid extract have all been recommended. *Surgical treatment* is indicated when there are signs of local pressure and in cases which do not show signs of improvement under medical treatment in from four to six months.

7. The patient must be in bed, isolated, with abundance of fresh air and sunlight, care must be taken to prevent bedsores, the mouth and throat must be kept clean, the diet must be suitable (milk, eggs, light soups, cornstarch, etc.), plenty of water; cool sponging or bathing; medicines are only to be given when clearly indicated; hemorrhage is best treated by withholding all food for ten or twelve hours, keeping the patient absolutely at rest, and by the administration of morphine; turpentine, also lead and opium pills have been recommended. The morphine checks peristalsis; the turpentine is styptic, the lead is also styptic. In severe hemorrhage, operation is indicated.

8. In *chronic interstitial nephritis*, the patient "must be cautioned not to expose himself to the inclemencies of the weather, to avoid all excessive muscular exercise and all mental worry; he must have his bowels open at least once daily (alkaline mineral waters, saline cathartics, occasional blue mass pill, etc.); and he must favor the action of the skin so as to relieve the subnormal cardiovascular-renal system; warm or hot baths are serviceable, but they are contraindicated if they cause unpleasant throbbings (increasing blood pressure). The diet is of the utmost importance, the duration of life probably depending more upon discretion in eating and drinking than upon any other factor. In many cases an exclusive milk diet for a time (four to six weeks) is desirable; and it may be repeated from time to time. In general the diet should be sufficiently varied to be attractive, it should be free from irritating qualities and readily assimilable, and the nitrogenous constituents should be relatively reduced. The meat allowance should not exceed 100 grams daily; a diet of ample fuel value should be constructed by adding a sufficiency of fats and carbohydrates; an excess of meat is said to favor the development of uremia; red and white meats are of equal value, and may be allowed in accordance with the patient's desires. As a rule, alcohol should be prohibited, although in some cases a little of the lighter wines appears to do no harm. In many cases the foregoing produces not only amelioration of the symptoms, but perhaps also arrest of the lesions: if so, other measures are not required." (Kelly's *Practice of Medicine.*)

Drugs are not of much value. (1) *Nitroglycerin* lowers arterial tension; (2) *iron* may be of benefit in pronounced anemia; (3) *aconite* may help when nitroglycerine fails.

9. *Ventilation of a school building* is intended to remove the impure air, to introduce pure air, and to prevent the accumulation of impurities due to respiration, perspiration, and combustion. About 65° F., is a good temperature for a school building.

10. The *main dangers to be apprehended in raw milk as ordinarily found in the market*: The milk may come from a diseased cow, it may be contaminated with dirt or other foreign matter, it may be diluted with clean or dirty water, it may be skimmed or otherwise sophisticated, it may contain disease germs, it may be kept in dirty containers, it may be exposed to high temperatures, it may be exposed to contamination by flies, etc.

Incurvate Little Fingers in an Afro-Aryan Child.—F. G. Crookshank reports the case of a female aged three years who had been under treatment for rickets somewhat irregularly during the past fifteen months. When first seen the incurvation of both little fingers were marked. This morphological character, although most often spoken of in connection with mongolism, was really, as had been noted by Keith and others, to be seen in the young of every primitive human race, and of all anthropoids. Its relation to mongolism is therefore general and not peculiar. The patient was the offspring of a male African negro and a female Cingalese, and was therefore without any trace of racial mongolism. A year ago her eyes most resembled those of a negro baby. They are now full, like those of the Cingalese and some other "Aryans."—*Proceedings of the Royal Society of Medicine.*

THE TREATMENT OF DISEASES OF VEGETABLE PARASITIC ORIGIN BY DEEP MUSCULAR INJECTIONS OF MERCURY.*

BY BARTON LISLE WRIGHT,

SURGEON, U. S. NAVY.

IN 1905 I first began the use of mercury in the treatment of tuberculosis, but it was not until 1907 that I had an opportunity to try out its value extensively. From then until 1910, when I was detached from the U. S. Naval Hospital for Tuberculosis, Las Animas, Colorado, to take my turn at sea, I published several reports of my results, some of which I will report later in this paper.

In 1910, while serving on board the *U. S. S. Nebraska*, I became intensely interested in Ehrlich's theory: That for every parasitic organism there is a chemical affinity, which if found and injected into the infected host, would destroy the infecting organisms, and therefore cure the specific disease.

His first successful experimental demonstration of this now well-known and recognized fact was made in connection with trypanosomiasis in mice by the injection of trypan red. After some experimental work he found that he could with great uniformity destroy all of the infecting organisms and absolutely cure the disease with one injection.

These experiments not only proved the correctness of his theory but developed two most important facts: (1) To produce the immediate curative effect the dosage of the initial injection must be extremely large; (2) Small and frequently repeated doses are not productive of rapid results, and when continued uninterruptedly unduly long, render the infecting organisms immune to their chemical affinity.

From my results in the treatment of tuberculosis with mercury, I was convinced that this metal was the chemical affinity of the tubercle bacillus. Granting this, why should it not bear the same relationship to the entire group of the vegetable parasites? After long consideration I was convinced that this must be the fact and developed my theory as follows:

For every vegetable parasite mercury is the chemical affinity, and when properly injected into the infected host will cure the specific disease. This is represented by a chemical formula as follows: (Vegetable antigen + Hg) + antibody + complement = complement fixation (cure).

I now believe that mercury has a dual parasitotropic action: First—primary or direct, in which the Hg by affinity unites with the organism and, without antibody, binds complement. Represented by formula as follows: Vegetable antigen + Hg + complement = complement fixation (immediate cure).

Total destruction of all the infecting parasites or of their virulency with immediate cure takes place. I am led to believe that this action is limited to the first few days after the onset of the acute infectious diseases, the period of time during which it will take place seeming to differ in each disease; in some it will be found to extend to the sixth day, in others probably only during the first or possibly the second day.

This is due, I believe, to changes in the organisms acquired by the prolongation of their existence in their new environment, by which they gradually lose most if not all of their affinity for mercury. I have never seen this action take place in a subacute or chronic infection.

Second:—Secondary or indirect, for the reasons noted above, the affinity of the organisms for Hg having been partially or completely nullified, instead of uniting with them, Hg stimulates the rapid production of specific antibody.†

This secondary action takes place in two stages and may be represented by chemical formulæ as follows:

First stage: Vegetable antigen + Hg = stimulated specific antibody production. Second stage: Vegetable antigen + antibody + complement = complement fixation (rapid cure). These reactions take place in the late stages of acute, and throughout the course of subacute and chronic infections, producing as a rule marked beneficial, with rapid but not immediate curative effects.

It is probable that both the direct and indirect actions of mercury in these infections occur in every case injected; under certain conditions one or the other predominating, the other taking a subsidiary part in the cure.

It is obvious that, in addition to the large dosage required, rapid absorption is equally necessary; therefore, one of the soluble salts of mercury is absolutely indicated.

In my work I have selected mercuric succinimide because I believe that a larger dose of this salt can be injected than of any of the others, and at the same time its parasitotropic action is many times greater than its organotropic advantages, which from experience I do not think the other soluble salts possess to an equal extent.

Mercuric succinimide gr. 1.8 = metallic Hg gr. 0.909.

In general, from what I have previously said, it is obvious that in the early days of an acute infectious disease the maximum dosage is solely in-

*Read before the New Hampshire Medical Society, May 13, 1914, and the Maine Medical Society, Portland, Me., June 11, 1914.

†At least two investigators have reported during the past two years, that when mercury is introduced into an infected animal specific antibody is rapidly produced.

dicated, while in the late days of these diseases, or in subacute or chronic infections smaller and more numerous injections are to be used.

During the early days of an average acute infection in an average adult male, the initial dose of mercuric succinimide should be gr. 9 5; if at the end of twenty-four or thirty-six hours there has been no improvement, or if, following improvement, there has been a return of symptoms, a second injection of from gr. 5 5 to gr. 6 5 should be given, providing symptoms of mercurialism have not followed the first injection. In the more virulent and quickly fatal of the acute infections, such as meningitis, whatsoever its etiology, the initial dose should be gr. ii.

In chronic infections (late days of acute and in subacute infections) in the average adult male the initial dose should be gr. 5 5 to gr. 7 5.

Succeeding injections should then be given with from two to four day intervals, in such dosage as will not produce mercurialism, until ten or twelve injections have been given, providing the symptoms have not disappeared in the mean time. When ten or twelve injections have been given, the treatment should be interrupted for from two to five weeks, in order that the mercury may be eliminated and that the organisms may not become immune to its action through its constant presence in their environment.

In some of the more persistently chronic infections the interval of time between injections should be from four to eight days.

In females the dosage should average from gr. 1 5 to gr. 2 5 less than in males.

Should symptoms of mercurialism appear at any time during the course of treatment the injections should be stopped at once and appropriate corrective measures applied, the injections being resumed if necessary upon the disappearance of these symptoms.

During this treatment the oral cavity and the teeth must have the utmost attention and be kept perfectly clean at all times, and the bowels moved freely daily.

Surgical asepsis must be carefully observed in every particular relating to syringe, needles, solution, and skin at site of injection.

The solution should be made of the strength of mercuric succinimide gr. 1 5 in sterile, distilled water ℥j iv. Inject deeply in gluteal muscles.

The only contraindication to this method that I know of is serious organic lesions of the kidneys.

With the foregoing in view, I invite your attention to the following cases:

Tuberculosis (Thirty-five cases).—Between 1907 and 1910, at the United States Naval Hospital, Las Animas, Col., I treated thirty-five officers with this disease. They were not selected cases of incipient character, but ranged from moderately advanced to far advanced; one was a case of acute pneumonic phthisis that two months previously had been originally diagnosed typhoid fever. In addition to the lung involvement, two patients had tuberculosis of the knee-joint, one of the knee-joint and lower third of the femur, and one had tuberculous ulceration of the larynx.

I discharged from the hospital nineteen of these cases, or 54.2 per cent., as apparently cured, including the two knee-joint cases, and the case of laryngeal involvement.

Since then but five of these patients have relapsed, one of whom has died. Of the sixteen not apparently cured, in ten the disease has been arrested, and the men are leading a fairly normal existence in various parts of the United States.

Among these the knee-femur case may be specially mentioned. When I operated on this patient in 1909 I removed the inner half of the lower third of the right femur, and this bone was in such bad condition that my colleagues and assistants urged me to amputate at the hip. This patient is now living in New York City with a sound limb, though a stiff knee-joint.

It is also of interest to note that in the case which began as an acute pneumonic phthisis, reaching me with a large cavity in the upper left lobe, the patient is now married and living in the State of New York.

Two of these patients showed no change, two I have lost track of, and two died while not under my care.

Lobar Pneumonia (Nine cases)[1].—Of these eight were immediate cures following one injection; the crisis usually began in about seven hours after the injection, in several within an hour or so after injection. In one the injection was given on the first day of the disease, in two on the second, and in six on the third day. The case that was not immediately cured received three injections, the fever falling by lysis on the fifth day, the involved area never completely undergoing resolution, and the evening temperature reaching 100° to 99° for the following two weeks, when a diagnosis of tuberculosis was made and the patient transferred from the ship to hospital. The following are fair examples of the eight cases of immediate cures.

W—— S. A., 27 years of age. Admitted on board the U. S. S. *Southery* by P. A. Surgeon L. H. Wheeler, U. S. N., at 9.00 A. M., December 3, 1913. Chill—followed by cough, severe pain in apex of right lung and extreme nervous symptoms. Temperature 101.5°, pulse 90, respiration 20. Diagnosis undetermined—lobar pneumonia suspected. 3.00 P. M., all symptoms increased, temperature 104°, pulse 126, respirations 40, transferred to hospital. December 4, 9.00 A. M., condition about the same, excepting that nervous symptoms had increased, and respirations were 68. Physical signs of consolidation of right apex. Surgeon F. M. Bogan, U. S. N., injected gr. 8/5 mercuric succinimide. Following this rapid crisis took place. Convalescence established which proved uneventful. (See chart No. 1.) Chart 2 represents similar results in a boy seven years old.

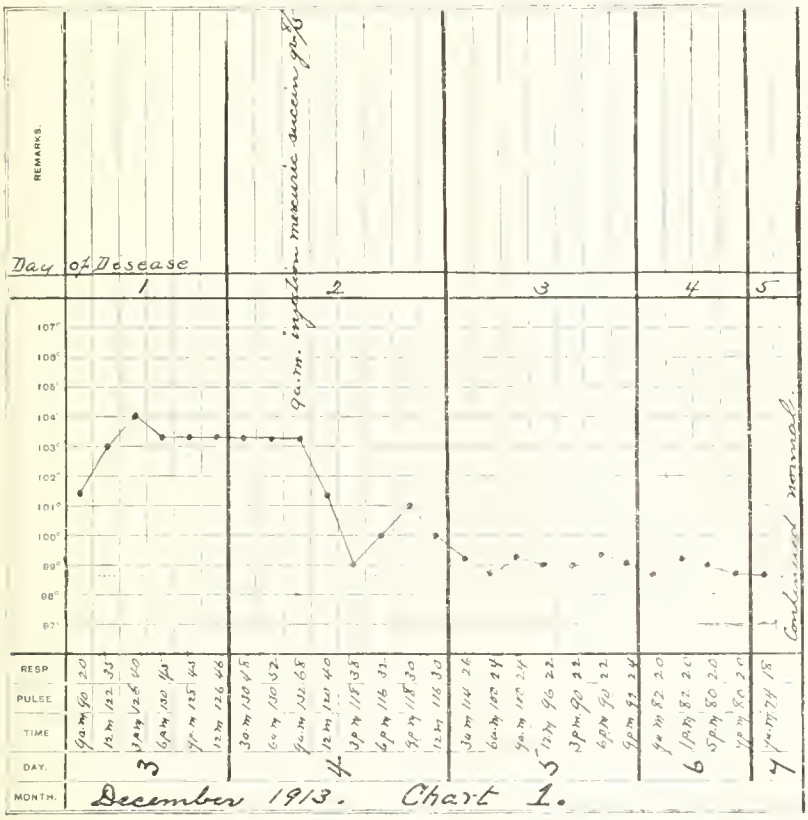
It seems probable in cases of pneumonia complicated by preexisting pulmonary disease, more particularly tuberculosis or syphilis, whether active or latent, that the direct immediate curative action of mercury will not take place; therefore when such immediate cure does not follow the initial injection in the early days of the infection, the possibility of such complications should be considered.

Lobular Pneumonia.—Six cases of this disease have been treated, in all of which an immediate cure was obtained. In one, the action was somewhat delayed, due in this instance to infection of both middle ears, the latter condition not, however, progressing to suppuration; this in itself was gratifying, showing the value of mercury in preventing or at least aborting a complication that usually persists for some length of time.

B——— W. W. Disease began rather suddenly on June 13, 1913. Slight chill at 8.00 A. M., followed by severe cough; at 8.00 P.M., temperature 101.2°, pulse 118, respirations 48. June 14, 8.00 A.M., about the same, expectoration free and characteristic, the entire area of both lungs presented the physical signs of lobular pneumonia. 10.20 A.M., Surgeon Bogan injected

mercuric succinimide gr. 7.5. Crisis began at 8.00 P.M., complete at 8.00 A.M., June 15. Convalescence uneventful. (See chart No. 3.)

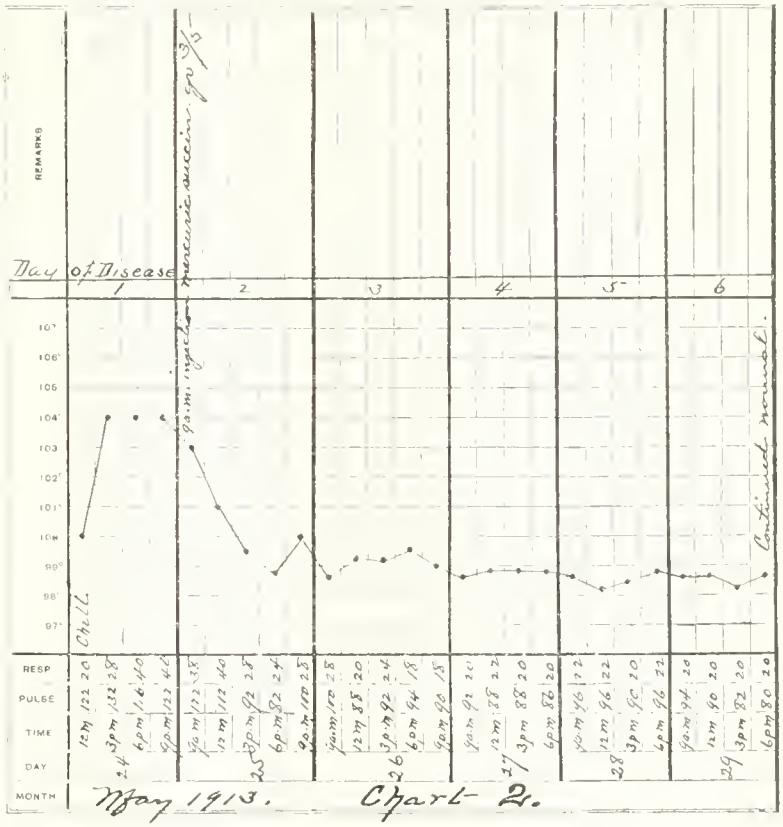
G——— J. Male. Age 4 years. First saw patient at 10.00 P.M., January 31, 1914. Cough developed the day before. Upper right lobe presented numerous subcrepitant rales, temperature 103.6°, pulse 132, respirations 36. Early lobar pneumonia suspected. Magnesium sulphate prescribed. By the following morning all symptoms had practically subsided and remained so during the day. February 2 all symptoms increased. 1.30 P.M., chill. P. A. Surgeon Wheeler and myself saw the case together at 2.00 P.M., diagnosis of lobular pneumonia made. 2.20 P.M., injected mercuric succinimide gr. 2 5. At 6.00 P.M., right middle-ear became involved. Patient extremely restless, and crying from severe pain in this part. Hot water bag locally. February 3, 6.00 A.M., apparently much worse, severe pain in right lung. Temperature 104.2°, pulse 130, respirations 48. Castor oil 15 c.c., administered. Improvement began by 9.00 A.M., and continued. February 4, all pneumonic symptoms disappeared, convalescence apparently established. 3.00 P. M. pain in right ear returned, asociated with rise of temperature, which rapidly subsided. February 5, without symptoms until midnight when severe pain developed in left ear. February 6, rise of temperature due to left ear involvement. February 7, no symptoms. February 8, up and about. February 11, cured. Visits discontinued. (See chart No. 4.)



Typhoid Fever (Five cases).—In this disease I am under the impression that the sixth day is the limit of time during which the primary or direct parasitotropic action of mercury may be expected to take place. Therefore, up to and including this day the initial injection should be gr. 9 5 in average adult males, with a second injection of gr. 5 5 or gr. 6 5 in twenty-four hours if required. From the sixth to the tenth day the initial injection may be gr. 9 5, but the second injection must not be given until seventy-two or ninety-six hours have elapsed. After the tenth day the initial injection in an average adult male must not be more than gr. 5 5, and succeeding injections not repeated more often than every seventy-two hours, the dose gradually decreasing at the same time.

The first case of this disease treated and reported was injected with mercuric succinimide gr. 7/5 on the seventh day of the disease, the temperature then being 103 ; by the following morning it was practically normal, but shot up to 102° during the day, when a second injection was given; a third and fourth injection resulted in normal evening temperature and the patient was out of bed and around the ship before the temperature would have reached normal in the usually treated case. In another week he went to his home on ten days' leave, and upon his return he presented himself with a large abscess in right lumbar region. Was transferred to hospital at Boston, Mass., where he was found to be suffering from "typhoid spine"; had he been injected earlier in the disease I think this complication would have been avoided.

The second case was admitted 7.00 P. M., March 25, 1912; stated that he had not felt well for a week or ten days. Complaint: headache, profound malaise, and constipation. Temperature 103.6°, pulse 95, respirations 20. Oleum ricini 30 c.c. Large movement of bowels 8.00 P.M. March 26. No change. Urine shows

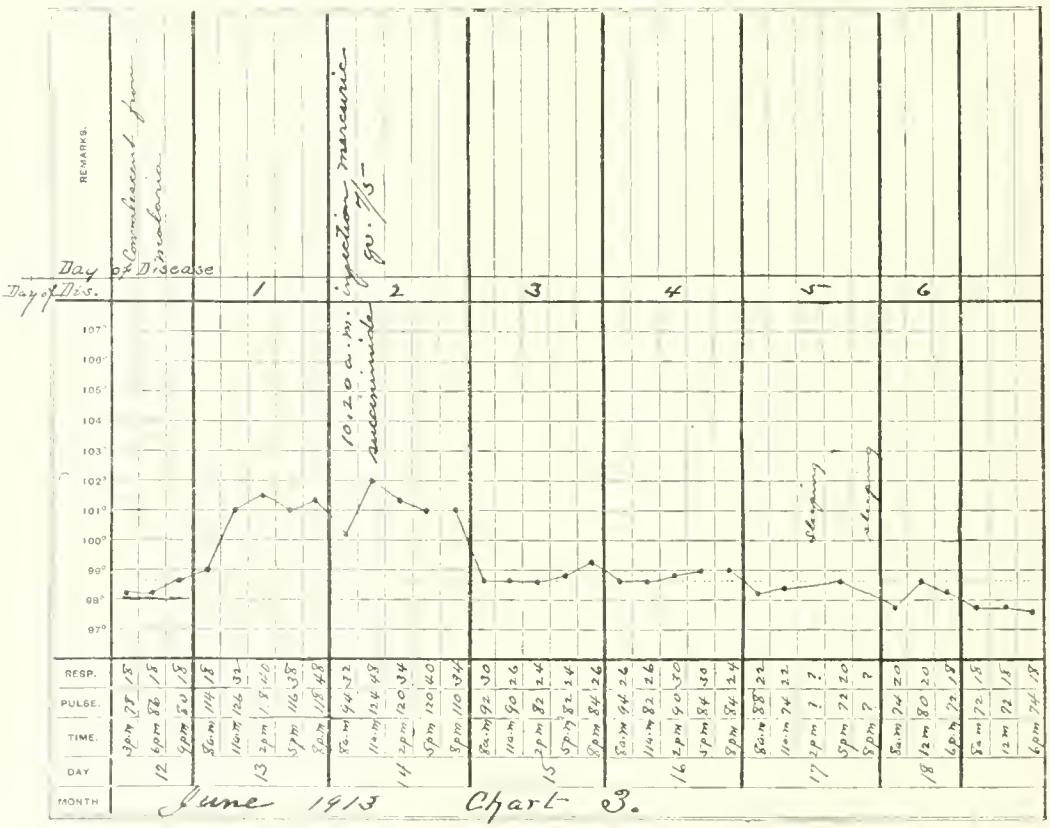


motile bacilli in large numbers. 10.00 A.M., temperature 104°, pulse 88, respirations 20. 4.00 P.M., injection mercuric succinimide gm. 0.11 (gr. 17/10), immediate improvement. 10.00 P.M. temperature 102°, patient felt much better. March 27, marked improvement. 8.00 A.M., temperature 100°, pulse 80, respirations 20. Termination by crisis. (See chart No. 5.) From this time on convalescence uneventful, discharged to duty March 31, 1912, having been under treatment just seven days.

Paratyphoid (1 case).—Hospital apprentice reported to me at 7.00 P.M., one evening in November, 1912, saying that he had been feeling badly for a few days and had kept a chart of his morning and evening temperatures, thinking he had tuberculosis. The chart showed the typical rising curve of typhoid, and that evening had reached 102° (4th day). He was placed in bed on liquid diet under observation. The following morning miscroscopic examination of urine showed numerous motile bacilli. Culture made and sent to the laboratory of U. S. Naval Medical School, Washington, D. C., for identification. That evening temperature reached 103°, and he was given gr. 9/5 of mercuric succinimide by injection. Following morning temperature was normal, but went to 102° in the afternoon when second injection gr. 6/5 was given. The following morning temperature was normal and remained so, and in three or four days he was returned to duty at his request. Some days later the laboratory reported the culture to be one of the Gartner group, none of which excepting *B. paratyphoid* B. would have produced the clinical symptoms of typhoid.

Cerebrospinal Meningitis (1 case).—In December, 1912, I was transferred to the Naval Hospital, Norfolk, Va., for treatment. Several weeks before they had received a case of cerebrospinal meningitis; the clinical symptoms and laboratory findings confirmed the diagnosis. Lumbar puncture with drainage and the introduction of antimeningococcic (Flexner's) serum was instituted at once and continued; the patient died during the sixth week of the disease.

About the middle of December his former room-mate was admitted to the medical ward, about 4.00 P.M., diagnosis undetermined, health record stating that he had been taken sick suddenly the day previous, with moderate temperature and delirium. On admission the patient was delirious, and presented all the classical symptoms of cerebrospinal meningitis; this diagnosis (etiology not determined) was made. Mercuric succinimide, gr. ii, was injected at 4.20 P.M., and the patient was transferred to the contagious wards. A telegram sent to Philadelphia for Flexner's serum. At 7.00 P.M., lumbar puncture was done and 90 c.c. of extremely cloudy cerebrospinal fluid under great pressure withdrawn. This contained a large amount of pus, a high percentage of albumin, and was positive for the *Diplococcus intracellularis*. The following morning the temperature was 99°, blood pressure 187, the delirium had disappeared and the patient recognized the fact that he was in hospital. 10.00 A.M., lumbar puncture was done, the spinal fluid was almost clear, almost free from pus cells, with a faint trace of albumin. In spite of the very marked improvement the medical officer in charge of the case felt that he must administer serum, which was done, at the same time gr. 8/5 of mercuric succinimide was injected into the gluteal muscles; rapid improvement took place. The following morning he was still further improved; a second dose of serum was injected into the canal after drainage, and gr. 5/5 mercuric succinimide injected into gluteal muscles. The following day his condition was nearly normal, lumbar puncture and drainage was done. The next day (fourth since admission) patient normal, convalescence established. Mercuric succinimide gr. 4/5 injected. Following this convalescence was uneventful, resulting in complete recovery in every respect.



Erysipelas (Two cases).—First case on fourth day had upper half of face, including nose and ears, involved, temperature 106°, profound toxemia, delirium. Injections gr. 8/5, 7/5, 5/5 on successive days. After first injection delirium disappeared, maximum daily temperature did not go above 103°. Reaching port, patient was transferred to hospital.

Second case on the first day; nose involved, temperature 102.5°, injection gr. 17/10 at 10:00 A. M., following morning normal, all symptoms disappeared. Cured and to duty in forty-eight hours.

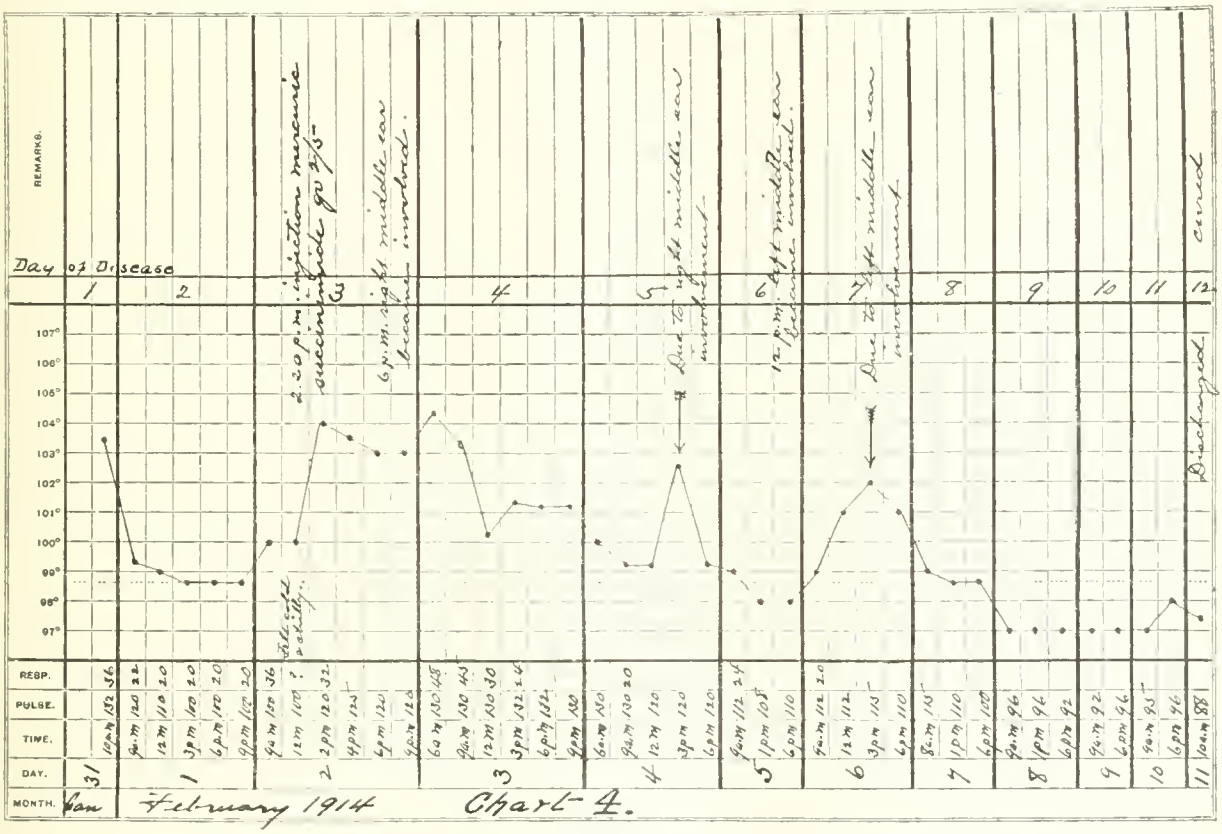
Infectious Arthritis (Thirty-nine cases).—*Acute Rheumatic Fever* (Eight cases).—In this particular infection where the normal alkalinity of the blood is known to be reduced, I have found it advantageous to correct this by giving fairly large doses of

potassium or sodium citrate or sodium bicarbonate either the day before or on the day of the injection.

The following cases are examples of the results that may be expected.

In the first case the patient was admitted to Naval Hospital, Portsmouth, N. H., September 8, 1913, from the U. S. S. *Hannibal*, as with acute rheumatic fever. A Wassermann proved negative and the diagnosis was confirmed. All previous treatment discontinued. Injection mercuric succinimide gr. 7/5. At this time both shoulders, both ankles, and the joints of left hand involved. Immediate improvement followed the injection. September 11, injection gr. 5/5; September 15, pain about disappeared, injection gr. 4/5; September 16, practically well. A few more injections were given as precautionary measures. The heart did not become involved and the patient returned to his ship and duty perfectly well.

In the second case the patient was a boy, aged 9 years; I first saw the patient on March 5, 1914, which was about the twenty-second day of the disease, and confirmed a diagnosis of acute rheumatic fever, complicated by a severe endocarditis. Examination of the lungs was negative. Previous treatment aspirin, for which I substituted methyl salicylate and sodium bicarbonate, the family not being willing at the time for me to inject. On March 8 developed severe cough. March 9, morning, upper right lobe presented harsh respirations and subcrepitant rales. 10.30 A.M., injection mercuric succinimide gr. 3/5, 3.00 P.M., physical signs of consolidation entire upper right lobe posteriorly (confirmed by my colleague P. A. Surgeon L. H. Wheeler, U. S. N.). Some time after 6.00 P.M., crisis began and was complete by 4.00 A.M. (See chart No. 6.) All pain practically ceased also. March 14 injection of mercuric succinimide gr. 2/5, following which temperature became normal and has continued so.



Chronic Articular Rheumatism.—Seven cases. The following case is an average example:

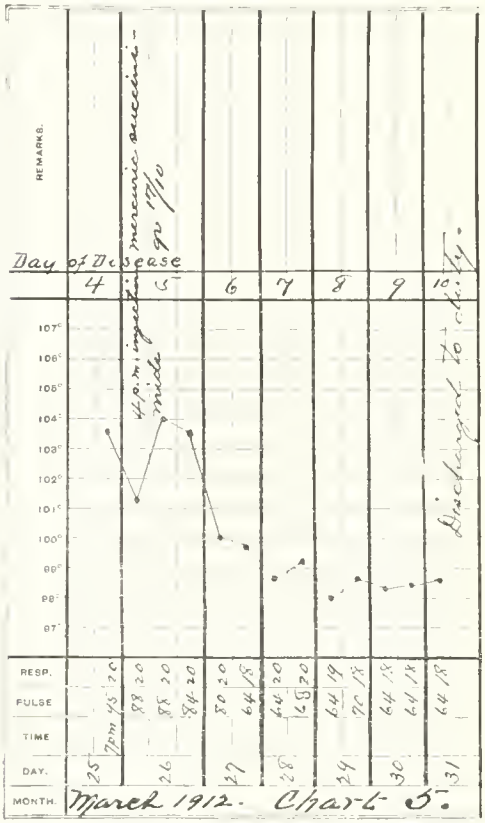
Mrs. ———, age 52, two adult children and one minor child. Perfect health until March, 1911, when she developed a severe attack of acute rheumatic fever, confined to bed until following June, since which time she has been a confirmed sufferer from chronic articular rheumatism. Came under my observation April 7, 1913. The heart, lungs, and abdominal viscera were apparently normal. Urine normal. Both knee joints, ankles, and the joints of both hands were considerably swollen, and extremely tender and painful. The lower limbs were edematous, and the abdominal cavity contained some fluid. The bladder was extremely irritable and painful. She was given the following injections of mercuric succinimide: April 11, gr. 5/5; 13, gr. 7/10; 16, gr. 3 5; 20, gr. 7/10. All symptoms disappeared by April 24, and she remained apparently well until May 12, when the bladder symptoms returned. Injections resumed as follows: May 13, gr. 9/10; 16, gr. 7/10; 20, gr. 7/10. Since this date she has remained perfectly well, has resumed her social duties and pleasures, eats freely of an unrestricted diet and is normal in every respect.

Gonorrheal Arthritis.—Twenty-four cases. The following case is an average example.

Disease first treated at the Marine Recruiting office, Topeka, Kans., March 7, 1911, since which time he has been practically under continuous treatment, and has had several negative Wassermann tests. From Topeka, he was sent to the Post-Graduate Hospital, Kansas City, Mo., transferred to the Naval Hospital, Philadelphia, Pa., where he remained 59 days, being discharged June 14, "condition improved." Did duty at the Marine Barracks, Philadelphia and New York, up to January 24, 1913, during which time he was receiving treatment. Admitted to the sick list on board the U. S. S. *Southery*, Portsmouth, N. H., February 1, 1913. Transferred to hospital, Portsmouth, N. H., March 4, 1913, as "not improved."

U. S. Naval Hospital, Portsmouth, N. H., March 4, 1913; patient walked with great difficulty. The action of the heart was very rapid and irregular. Salol gr. xx, *t.i.d.* March 25, no improvement. April 7, rapid pulse continued (150 9.00 A.M.), no relief from pain. May 3, 1913, Surgeon F. M. Bogan requested the writer to ask for a survey on this man, with the view of having him discharged from the service, or in lieu of that to see the patient in consultation and suggest a line of treatment. Patient was bent forward at the hips, unable to extend the trunk into a vertical position. The right knee, considerably swollen, flexed, and fixed at an angle of 60°, was extremely tender and painful. The left knee and both ankles were involved, the bladder was extremely

irritable. Temperature 100 , pulse 120, respirations 24. Weight 149 lbs. (normal 165). Injections of succinimide of mercury as follows: May 5, gr. 7/5; May 7, gr. 6/5; May 8, mercurialism; 11, improved, temperature 98°, pulse 82, injection gr. 9 10; May 15,



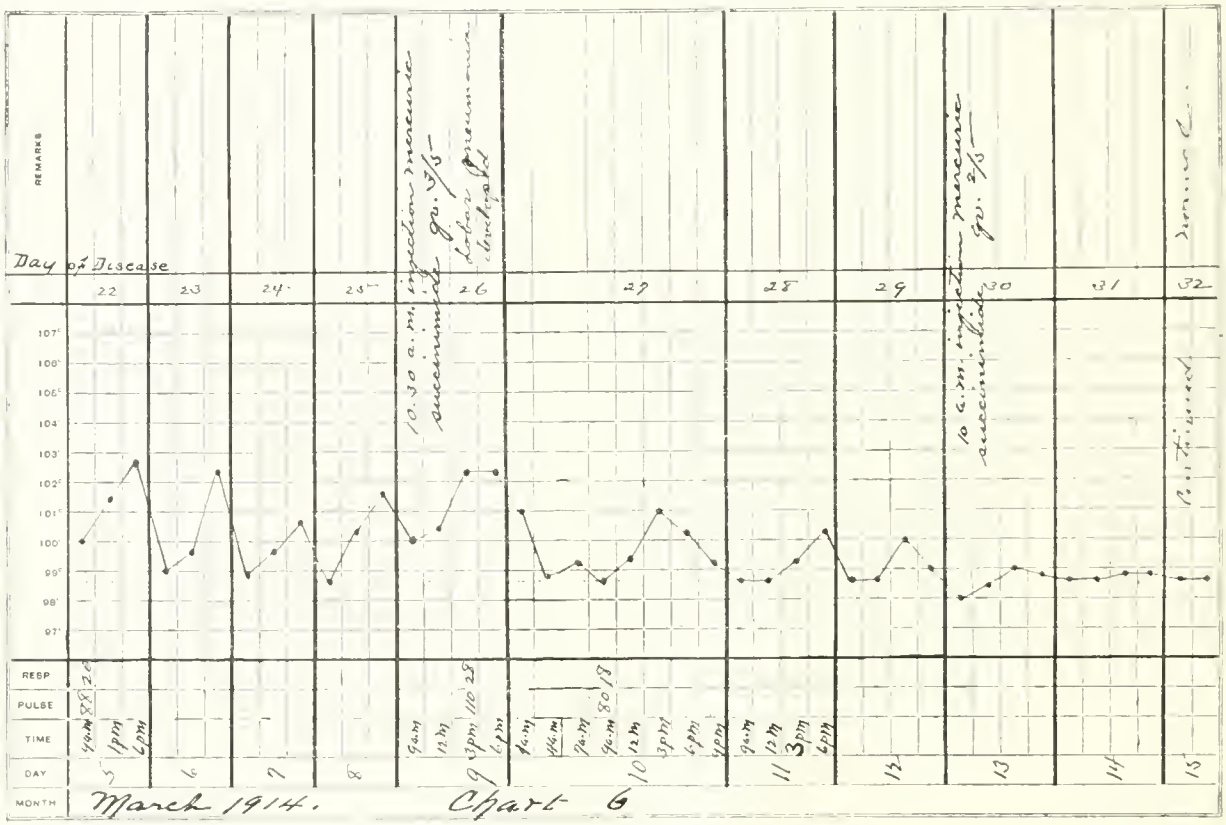
marked improvement, all pain practically disappeared; the swelling of the right knee had disappeared, there was perfect motion in the joint; he was able to stand perfectly erect and walked with great ease, injection gr. 4/5; May 20, injection gr. 3/5. For the first time in two years he felt perfectly well, there was no limitation of motion in any joint, temperature and pulse were normal, weight 163 pounds. Since this date he has remained perfectly well. Lack of time prevents further details.

In addition to the above there have been treated by my method 15 cases of acute tonsillitis, all immediate cures; 5 cases of epidemic catarrh, cures; 1 case acute cystitis (staphylococcic), immediate cure; 3 cases chronic cystitis (gonococcic), 2 to 3 injections (rapid cure); 10 cases furunculosis, 2 to 3 injections; 32 cases of colon bacillus infection, rapid cures; 1 case acute pleurisy, immediate cure; 2 cases lymphangitis, immediate cure; 4 cases cellulitis, 2 immediate and 2 rapid cures; 1 case of mumps, right parotid swollen and painful, left parotid painful, injected first day gr. 9 5, immediate cure; Vincent's angina, 1 case, rapid cure.

In addition to these cases, several independent foreign investigators claim and report the most excellent results from the use of mercury in the treatment of diseases of vegetable parasitic origin.

In October, 1912, Doctor Charles Souligoux, surgeon on the staff of the Hospital of Paris, Paris, France, reported to the Surgical Society of France 144 cases of puerperal septicemia treated by deep muscular injections of gr. 1 6 of mercuric cyanide daily, with but three deaths. This report was published in detail by his assistant, Doctor Giru, in the *Archives de Chirurgie* of November 25, 1912.

In the course of his practice in Kiev, Doctor P. Krohl[6] noticed that women who were undergoing a mercury treatment or who had recently finished one had a completely normal puerperium after a normal delivery or an abortion, in spite of the fact that they lived under the most unfavorable hygienic conditions. *"Moreover I noticed that syphilitic patients during and after a mercury treatment had a peculiar power of resistance to infection of every kind. Not only did they not take the ordinary infectious diseases, but in cholera epidemics they seemed immune to that infection."*



With this in view he started experimental work with seventy-eight rabbits, and an extremely virulent culture of streptococci. Dividing the rabbits into four groups—the first group of controls injected with streptococci but not mercury; the second group before infection with the streptococci had immunizing injections of benzoate of mercury; the third group received injections of mercury at the same time as injections of streptoccoci; the fourth group did not receive injections of mercury until after the appearance of the symptoms of sepsis at various stages of its developments.

The animals of the first group all died of general septicemia, and in their blood large quantities of streptococci were found. The results obtained in the remaining three groups led Krohl to the following conclusions: "Giving a series of injections of benzoate of mercury in small doses (1.5 mg. to kilogram of body weight) renders the organism for a time, the duration of which is not accurately determined, not susceptible to infection with streptococci. A smaller number of injections in larger doses gives the same result. *The giving of small doses of mercury before the beginning of the disease, or the injection of large doses in the early stages of the disease, prevents the development of general septicemia.* Too small and too late injections of mercury do not help the organism in its struggle with infection, and the sickness ends in death from general septicemia." Upon these grounds he resolved to use benzoate of mercury in his practice, and reports a number of cases, the following being an example:

"N.——K. 29 years old. Three days after her second delivery had a chill, temperature 102.6°, pulse 128, skin dry. Patient restless, very thirsty. Thoracic organs normal; mammary glands also; abdomen not sensitive. Uterus well contracted. Discharge normal and in sufficient quantity. No external injuries of the genital organs. Intestines empty. On the first day injection gr. 1/6 hydr. benz., in the gluteus. Second day temperature 102.7°, pulse 120, injection repeated. Third day temperature 100.9°, pulse 112, injection repeated. Fourth day, temperature and pulse normal."

Krohl states: "I have observed a great number of such cases and they all showed the same favorable results, with the exception of those in which the injections were given too late."

During the past year Siemerling has reported excellent results in the treatment of meningitis by inunctions of mercury as recommended by Quincke.

On page 259 of the March (1914) number of *Progressive Medicine* Ruhräh cites the excellent results obtained by Carlo, Singer, Maragliano, and others in the treatment of rheumatism by the "Baccelli method," which consists in the intravenous injections of bichloride of mercury.

Conclusions.—I believe that my results, coupled with those of the distinguished foreign observers above mentioned and of my colleagues in the Naval Medical Corps, mentioned in this paper, demonstrate the superlative value of mercury in the treatment of the infection cited, and make it strongly probable that its action in the case of all diseases of vegetable parasitic origin would be equally and as promptly curative.

The secret of success is the administration of the largest dose possible, at the earliest moment possible after the onset of the disease.

SOME RADIUM THERAPEUTICS.*

BY JOSEPH B. BISSELL, M.D.,

NEW YORK.

So much has been written recently, in the public prints as well as in the medical journals, concerning radium and its therapeutic uses that a few moments spent in reporting experience with this substance may be of interest.

Radium is a metallic element closely allied to barium. As is well known it was isolated some years ago in the laboratory of Madame Curie, in Paris. It has a very high atomic weight and possesses the property of radioactivity. When isolated it is most difficult to keep pure as it reacts with air, forming the oxide, the nitrate, and the carbonate. It is a metal which is exceedingly reactive and on account of its activity is only to be obtained in the form of its salts, the bromide, the chloride, the sulphate, and the carbonate. The first two are soluble in water while the sulphate and the carbonate are insoluble. These salts are all strongly reactive, and their activity depends upon the content of the radium element in each.

The most important property of radium is its radioactivity. It is upon this quality its therapeutic effect depends. This radioactive energy is utilized in various ways. Radium may be employed locally, usually in the form of a sulphate with an admixture of barium, mesothorium, or both, or it may be administered by mouth in solution as the chloride, or the bromide salt, or by its inhalation, the so-called emanation method, as well as by intravenous injection. These methods have given definite physiological effects, and the therapeutic results from them have been demonstrated. Radium is also applied in other ways. Radium pads, radium applicators, radium earth poultices, radium ointments, and radium baths, have been used with good results. To the general public the application of radium means its use in a sealed tube for the destruction of malignant growths or cancer.

The action of radium depends upon its property of spontaneously emitting radiations. These radiations are capable of passing through opaque substances. This is accomplished by means of spontaneous atomic disintegration. Radioactivity is characteristic of all the radioactive elements. It is a spontaneous disintegration of the atoms, and during this transmutation rays are shot out. The

*Read before the Orange Mountain Medical Society at Orange, N. J., March 20, 1914.

rays which are utilized in therapeutic use are the alpha, the beta, and the gamma rays. Each of these is more penetrating than the other in the order given. These rays shoot out with terrific velocity from the disintegrating atoms. The alpha and beta rays are minute particles of matter electrically charged, with comparatively feeble penetrating powers. The gamma rays resemble in many respects physically the *x*-rays. They have a high penetrating power.

Each of these three groups of rays, and their subdivisions have therapeutic value, but the gamma rays, or some of the gamma rays, are much more useful surgically. The gamma rays are capable of quite deep penetration and they require as much as ten centimeters thickness of lead to absorb them completely. The alpha rays, on the other hand, may be completely cut off by a very weak, intervening substance, such as a sheet of ordinary notepaper.

In spite of their softness, however, these rays will produce inflammation and necrosis of the skin if it is exposed sufficiently long to the effects of the unscreened radium. The beta rays may be cut off by a screen 25 millimeters thick of aluminum or 5 millimeters thick of lead.

Screening is what is known as the prevention of certain rays reaching the object by interposing a opaque substance between it and the radium. These substances differ for the different rays: for instance, rubber tissue may screen off the alpha rays, while lead or platinum is used for the gamma rays. Lead of considerable thickness may be used to shut off the more penetrating of the gamma rays. Radium salts are placed first in a sealed glass container, this in turn is placed for safety in a tube made of lead and silver or lead and platinum, with very thick walls. The greater the quantity of radium the thicker must be the walls of this tube in order to cut off the gamma rays and thus prevent injury to the person handling the tube as well as to the subject of its application. There is a wide variation in susceptibility to the effects of radium of the various normal tissues of the body. The eye and the nervous tissues have comparatively slight sensitiveness. Other parts, like the ovary, are affected very easily. As a rule pathological tissues are more sensitive than normal ones. New growths differ considerably as to their degree of resistance.

Epitheliomata require larger doses than some other morphological tissues. The nearer the surface of the body new growths are, whether benign or malignant, the easier can they be destroyed. Growths of the mucous membrane of the mouth require large doses and are quite difficult to cure. The effect of radium extends only to the depth the rays reach, therefore the larger the mass to be attacked the larger must be the quantity of radium used and the more extensive and continuous its application. Cross-raying consists in dividing the radium into portions and placing one each on opposing sides of the tissues to be affected. If possible a tube of radium is placed in the tumor mass. The results of treatment may be complicated by an erythema or even a severe burning or by extensive edema. This is usually due to inefficient screening or to too long an application where a large dose was imperative. As a rule this burning or edema does no harm aside from the discomfort and the long period of time required to relieve it. The passage of the soft beta and alpha rays through the screen have appeared occasionally to increase the rapidity of the growth of the cancer. The longer the application of the radium the greater the possibility of these undesirable reactions.

Many factors enter into the problem of the successful use of radium. The technique of filtration, the length of time of the application, the amount of salt necessary to be used, as well as its form and shape, the location and position, the susceptibility of the tissue involved, its pathology, the varying degrees of resistance of the different normal and abnormal tissue cells, as well as other chemical and physiological and biological facts must be understood before the therapeutic value of this element can be determined. Until experience has given us more knowledge, reports of the results of treatment must continue to be unsatisfactory in many cases; not because radium is not capable of doing the things we expect, but because as yet we do not know how to make proper use of it.

In Europe and in England knowledge of the therapeutic value of radium is greater because of the greater experience and the greater length of time it has been in use there, as well as the larger quantity of material of which these countries have had the benefit. The amount of literature published on the subject in England, France, Germany, and Italy is quite extensive. The Austrian government has ordered the producers of radium to double their output this year in order that its therapeutic advantages may be thus increased.

Not content with using what radium could be obtained in Europe, the various laboratories and hospitals on the other side have imported comparatively large quantities of the metal from this country. Aside from the radium itself the effects of the radium products have been made use of and carefully studied in other diseases than that of cancer in many of the clinics and hospitals of Europe.

Dominici radiated small joints affected with gonorrheal rheumatism with 5 to 10 milligrams and with poorly acting salt. Reports of results have been secured with one milligram in granuloma and trachoma. A scrofulous gland was reported to have been cured with one milligram, the tube being embedded 23 days. Deafness was treated with from 1 to 2 milligrams, uterine hemorrhage was stopped with 4 to 10 milligrams, goiter with 10 milligrams, sarcoma with 20 milligrams, fibroids with 27 milligrams. In internal medicine no less an authority than von Noorden recommends its use in many pathological conditions.

For the purpose of the injection radium in the form of the bromide is dissolved in saline solution. This is enclosed in a glass ampule put up aseptically in the laboratory. Each ampule contains 50 micrograms of the salt, but if desired 25 micrograms or 100 micrograms can be easily put up in this glass container.

In cases where radium is prescribed by mouth the dose is 1 microgram of radium bromide in solution. Each dose is put up in a separate bottle. It is taken three times a day before meals. A special glass or straw tube comes with each bottle. In some cases bath water was also used, and where the joint pain was very severe radium pads were applied. In every patient with arthritis efforts were made to ascertain the cause of the joint infection, and if possible to remove it. Blood pictures were taken before and after treatment. The blood pressure and the coagulation time of the blood were taken before and after each injection. Accurate observation of symptoms and functions

were noted before, during, and after treatment, in order if possible to draw definite conclusions as to the value of radium therapy.

Case I.—Mrs. S., widow, 57 years old. This patient had suffered for the past 15 or 20 years from various forms of gout or rheumatic affections of the joints and muscles. The preceding winter had been a particularly painful one for her. All the usual antirheumatic remedies, such as aspirin, salicylates, etc., had been tried upon her with indifferent results. No cause could be ascertained for these attacks, unless it was due to heredity. February 12, during an attack of pain with swelling and tenderness at the right ankle joint, after trying the usual remedies without relief, she was put on radium drinking water, three doses a day, and treatment was kept up for several weeks. Relief from the pain was distinct and immediate, and within 24 hours after beginning the treatment she was able to walk about without distress and without limping. There was no local treatment, and no other joints were affected, although usually the disease migrated from one joint to another and she had been quite miserable for a long time in all her previous attacks.

Case II.—Mrs. S. B., 46 years old, dressmaker. September 16, 1913—Multiple rheumatoid arthritis of three years' standing; patient confined to her bed for the preceding two years; principal joints affected were the knees, ankles, wrist, elbow, and shoulders as well as the carpometacarpal and tarsometatarsal and phalangeal articulations. No fever, pulse normal, but severe pain continually present, aggravated by any attempt of flexion of the joints. No history of cause of infection obtainable, but the patient had bad teeth, many of them being broken off, and the roots were decayed and tender. She had also Riggs' disease of the gums; *x*-ray plates showed disease of the roots of several of the teeth and small abscess points in the sockets. Patient had been treated for rheumatism by various remedial measures, a series of injections of pituitrin as well as pneumococcus vaccines, both of which proved nonbeneficial. Under anesthesia patient had adhesions of both knees broken up thoroughly, and the legs put in plaster. The result was a much worse condition of pain and swelling than before the operation. Patient had a blood pressure of 142 to 158. Red blood cells averaged about 3,800,000; white cells 6,250; polynuclear cells 84 per cent. Coagulation time about 10 minutes; hemoglobin 72 per cent. Patient is unable to use her hands and fingers without pain. The other joints are also very painful. The pain is so severe that at night her sleep is broken. Her appetite is poor. She is losing in weight, and her mental condition is depreciating.

On December 21, 50 micrograms of radium bromide solution were injected into the basilic vein of arm. Two weeks later this injection was repeated. Again two weeks after this 100 micrograms were injected as above. Two succeeding injections two weeks apart of 50 micrograms each completed her treatment to date, March 16. Thus a total of 300 micrograms of radium were injected into the blood with the following results: Within a few hours after the first injection the patient was able to use her hands and fingers without pain. Pain in the other joints slowly disappeared. She gained in weight, and she has acquired a varied amount of improvement in all the joints and muscles. This was most marked in the fingers, hands, and wrists. She is now able to use her fingers in her avocation as dressmaker, sewing, threading needles, tying knots, etc. Her shoulder joints, which were apparently fixed, are now movable in all directions without pain. The joints of the feet, ankles, and knees have shown the least amount of improvement in motion. Pain and tenderness, however, are markedly less. The patient, for the first time in many months, is able to be out of bed in a rolling chair. Her appetite has improved, and naturally her general health is very much better. Swelling is still present in many of these joints as well as considerable deformity. She felt sleepy after each injection.

The blood picture shows startling differences. The red blood cells were increased to 4,500,000 immediately after the first injection, and have remained at about that average. The white cells have slightly increased, averaging about 6,800. The polynuclear cells have decreased, ageraging about 78 per cent. Lymphocytes have markedly increased. Coagulation time was lessened to an average of three minutes. Hemoglobin is increased to 90 per cent. Blood pressure now runs from 136 to 132 and is at times down to 98.

During the treatment the patient's mouth and gum condition was also cared for carefully. The roots and decayed teeth were extracted and the Riggs' disease was treated, until at present her mouth condition is fairly normal as far as any inflammatory process is concerned.

Case III.—M. F., male, 31 years old. Rheumatoid arthritis of six years' standing. All his joints are involved, especially the knees. He had marked trismus of the jaws and was unable to swallow any food except fluid because of inability to masticate. The vertebral joints were all more or less fixed, every joint was painful on motion and more or less tender to touch. The patient was troubled with frequent and painful urination. He had to lie almost continually on his back, his head propped slightly on pillows. He was a typical picture of misery and suffering. Blood count before the first injection showed red blood cells 4,328,000, white cells 8,000; polynuclear 87 per cent.; hemoglobin 90 per cent; coagulation time 12 minutes; blood pressure 114. This was on February 20. On February 24, 50 micrograms of radium bromide were injected into the median basilic vein. There was no reaction following this injection. The following day the blood count was: red blood cells 4,888,000; white cells 9,200; polynuclear 81 per cent.; hemoglobin 90 per cent.; coagulation time 11 minutes; blood pressure 104. The trismus was markedly less; pain about the joints much less marked; mobility freer; sleep much improved; urination interval lengthened, and voiding much less painful. March 19, again 50 micrograms of radium injected into the same vein. On the following day all the symptoms above mentioned were greatly improved. Appetite was much better and sleep almost normal. In the first twelve hours after this injection a slight reaction occurred; slight chill, temporary increase of pain in the knees, and a headache, all of which passed off in a few hours. On the second day after this injection the blood count was: red blood cells 6,104,000; white cells 10,000; polynuclear 50 per cent.; hemoglobin 100 per cent; coagulation time 9 minutes; blood pressure 110. The patient's improvement at the end of three weeks after the second injection continued. The most striking evidences of the result of the radium were relief from pain, ability to sleep, and improvement in appetite. A great change was noticeable in the motion about the jaw joints. Before the injection the patient could separate the upper and lower jaws only about enough to insert the handle of a teaspoon flat. Now he is able to take food into the mouth and chew it. Also he is able to protrude his tongue so that observation can be made of it. This patient is taking radium drinking water containing one microgram of radium bromide three times a day, and it is expected that the improvement will continue after further intravenous injections. The etiology in this case is unknown.

Case IV.—A. W., aged 32; multiple rheumatoid arthritis, principally affecting the knee and shoulder joints. He has a history of bad tonsils, which were removed several months ago. He is unable to work at his trade as a mechanic because of pain and tenderness in these joints not responding to medical treatment. These attacks have been coming on for two years, each one worse than the last. February 10, the day before his first injection, the blood picture was: red blood cells 3,870,000; white cells 7,200; polynuclear 78 per cent.; hemoglobin 80 per cent.; coagulation time 10 minutes; blood pressure 155. He had two injections, two weeks apart, beginning February 11. He had immediate improvement in his blood picture, in coagulation time, and in blood pressure, the latter dropping on the second day to 125. On March 11, four weeks after the first injection, the blood picture was as follows: red cells 5,200,000; white cells 6,800; polynuclear 68 per cent.; hemoglobin 100 per cent; coagulation time 5 minutes; blood pressure 120; joints much improved; tenderness less; motion good. Patient is able to walk about, and has been discharged from the hospital to go back to work within the last few days. Following the injection he complained of sleepiness.

Case V.—Mrs. E. H., aged 41; postoperative arthritis of right knee. This patient was operated on in the usual manner for fracture of the patella October 5, 1913. She did rather badly after the operation, having a good deal of pain in the knee, swelling and edema of the foot and leg. Slight infection of the skin wound was found on removal of sutures, with well-marked involvement of the structures of the knee joint. Under careful treatment the acute symptoms disappeared

without suppuration taking place, but the joint remained swollen, tender, and painful for a number of weeks. X-ray picture showed at the end of two months the patella fragments united and some evidences of osteitis in the middle of the fibula as well as marked thickness of the cartilaginous structure. On March 1, 1914, the patient was still in bed with a posterior moulded splint supporting her right knee joint, well marked edema of the foot and leg, great tenderness and pain on motion of the joint, and considerable swelling and redness over the contour of the right knee. On March 8 the blood picture showed: red blood cells 4,800,000; white cells 12,000; polynuclear 55 per cent.; hemoglobin 80 per cent.; coagulation time 7 minutes; blood pressure 100. The usual injection of radium bromide was made on March 9. The second day after the red blood cells were 5,176,000; white cells 11,800; polynuclear 62 per cent.; hemoglobin 80 per cent; coagulation time 6 minutes; blood pressure 98. Pain was markedly alleviated. There was slight increase in the mobility of the joint, and at the end of the fourth day reduction in the swelling over the knee itself was quite noticeable. The patient's general condition was markedly improved, probably due to better sleep. March 16 the injection was repeated and on March 19 all the above improvement was retained and increased. The red cells were now 5,600,000; white cells 7,800; polynuclear 77 per cent.; hemoglobin 85 per cent.; coagulation time 3½ minutes; blood pressure 92.

Case VI.—Mrs. M. F., aged 40; arthritis of left hand and wrist. Patient had several attacks of rheumatism in various joints at different times preceding her admission to the hospital; had also a history of endometritis four years previous. Present illness began October 31, 1913, with chill, fever, pain, and swelling in various joints, all of which cleared up under medical treatment except the left wrist and hand. At present, February 28, all the fingers and thumbs are stiff and painful, wrist joint swollen and tender, and motion almost restricted because of the pain. In January a gonorrheal fixation test was positive. Various and persistent methods had failed to produce any improvement, and the patient was turned over with a diagnosis of gonorrheal rheumatism. Patient was given 50 micrograms of radium intravenously on March 5 and also on March 16. Before the first injection the picture was: red blood cells 5,392,000; white cells 18,000; polynuclear 66 per cent.; hemoglobin 90 per cent.; coagulation time 8 minutes; blood pressure 115. After the second injection the red blood cells were 5,800,000; white cells 10,000; polynuclear 48 per cent.; hemoglobin 100 per cent.; coagulation time 6 minutes. The blood pressure dropped to 98, afterward ascended to 100, and remained at that point. Of the symptoms, pain was alleviated within the first 24 hours; swelling on March 18 much reduced; movement in the fingers and at the wrist joints markedly increased. Patient's appetite and general condition improved and she is able to make use of her hand to the extent of picking up objects, sewing, rolling bandages, buttoning and unbuttoning her clothes without pain. She was able to sleep much better after the injections.

Case VII.—H. B., male, 50 years old; with a history of arteriosclerosis and nephritis, with a high blood pressure of 230. He was given 50 micrograms of radium bromide with the object of seeing the effect upon his blood pressure. His only reaction was a slight headache. His blood pressure at the end of four hours was 210; at the end of eight hours it was 190. The following day it was reduced to 160, where it remained for about a week, when he died of his nephritis. This man was hopeless when I first saw him. He was waterlogged with ascites and suffering from alcoholism. The radium was given to him simply to see the effect upon his very high pressure.

Two cases of arteriosclerosis at Bellevue also received one injection each in order to study its effect upon blood pressure. One was a heavy beer drinker with contracted kidney, whose pressure was reduced from 156 to 140 in the first 24 hours. The blood pressure of the other was reduced from 160 to 140 in the same length of time by the injection of 50 micrograms.

No reaction was noticed following the injections except in one case a severe headache the next day, and in another case slight chill, fever and increase of pain about the joints for two hours. No local reaction was noticed in any of the intravenous injections. Most of the writers on the intravenous use of radium record an increase of pain and swelling about the affected joints, but with the one exception mentioned above it did not occur in my cases.

In the literature of radium treatment a reaction is considered to be rather a good sign and improves the prognosis.

From a study of these nine patients the following facts concerning radium therapy may be assumed: Radium injected into the veins relieves pain; it improves the blood picture in anemic and cachectic patients; it causes absorption of deposits around chronically infected joints; it reduces high blood pressure, lessens the coagulation time, and has a certain definite effect as a hypnotic.

46 West Fifty-fifth Street.

COW'S MILK, RAW AND HEATED.*

By E. W. Titus, M.D.,

Washington, D. C.

The production and distribution of milk engage the attention of no small part of our population. The use of milk is general and not limited to any class or locality, and it is regarded as a necessity by almost every family. Milk is responsible for more sickness and deaths than perhaps all other foods combined. It is perhaps used to a greater extent in this than any other country, about 16 per cent. of the average dietary in the United States consisting of milk and milk products. The question of sanitary milk to the American people is therefore an especially pertinent one.

The dairy cow fills a unique place under the conditions of our present civilization, since her living body is the source of milk, the most important of all human foods. Containing, as it does, all of the essentials of a perfect ration, it is capable of almost universal use. Owing to its facility of ingestion and comparative ease of digestion, it not only constitutes an important article of diet for the sick and convalescent, but is even of greater importance as a substitute for mother's milk in infant feeding. Considering the fact that those most dependent upon this food, the sick and convalescent, infants and children, constitute that part of the community suffering the greatest injury from the use of a food impaired in its nutritive content, one can readily realize the essential importance of insuring the community a supply of pure, wholesome milk. For these reasons our best endeavors are challenged in the consideration of sanitary milk and its relation to the public health.

Classification of Milk.—In general there are two great classes of milk, raw and heated. The term raw milk is used to indicate milk in its natural state, not subjected to treatment. By heated milk we understand milk which has been subjected to different degrees of temperature, including pasteurized and sterilized or boiled milk.

Bacterial Content.—In taking up for study raw milk, it is interesting to note the bacterial content, organisms concerned and modes of contamination.

Milk delivered in cities contains a vast number of organisms. We know that milk, freshly drawn from the udder of the cow, even when the most careful precautions are taken against contamination, always contains bacteria, varying of course

*Read before the Galen Society of the District of Columbia, March 16, 1914.

with different animals, but usually so small in numbers that it is unimportant. As a culture medium, milk deserves a high rank, and when it is kept under improper conditions it is easily understood how bacteria can multiply. Statistics show that during the summer of 1906 the general milk supply of Washington averaged over twenty-two millions bacteria to each cubic centimeter. Such enormous numbers mean but little, for we know that disease is due to agencies and conditions other than merely the presence of large numbers of bacteria. On making comparisons, it will be found that few substances contain such myriads of germ-life as are often found in milk. According to Russell, it will almost always be observed that milk, when it is consumed, is richer in bacteria by far than the sewage of our large cities, a fluid popularly and rightly supposed to teem with germ life. The number of organisms in milk is not so important, as are the kind and nature of the bacterial products. With cleanliness and the liberal use of ice, the total number can be kept down, thereby affording a mode of protection against the harmful species and their toxic products. When the bacterial content is kept low, the milk will contain proportionately few or no dangerous varieties. Owing to the fact that most of the specific pathogenic bacteria which sometimes contaminate milk grow best at or about body temperature and not at all at low temperatures, the necessity for keeping milk at a low temperature becomes apparent.

Age of the milk is an important factor in influencing bacterial growth, but clean milk may contain more bacteria when it has been several hours in a warm place, than dirty milk when fresh or even after two or three days, providing it has been kept at a low temperature. It is not within the scope of this paper to discuss the various organisms found in contaminated milk or the modes of contamination, but it may be stated that certain diseases such as tuberculosis, diphtheria, typhoid fever, septic sore throat, and many intestinal disorders are definitely proven to be borne by raw milk. Among the common sources of infection are ill health and lack of cleanliness among dairy employees, unclean utensils, air and dust of stables, and a contaminated water supply for the dairy. Again milk may become contaminated while still in the udder, through infection present in the cow.

Heated Milk.—Under the general class, heated milk, we will consider milk which has been subjected to artificial heat. This class includes what is generally known as pasteurized and sterilized milks. The term "pasteurized" milk is misleading and confusing, being often construed to mean a superior quality of milk. It really means heated milk and is not necessarily synonymous with "clean milk," "good milk" or "pure milk." Rosenau suggests the discontinuance of the term "pasteurized milk," and in its stead the term "heated milk," stating the degree of heat, length of exposure to the heat, and date. Pasteurized milk as defined by the New York milk committee is milk that is heated to a temperature not less than 140° F., for not less than twenty minutes, or not over 155° F. for not less than five minutes, with rapid cooling immediately to 50° F. or below, and at which temperature it is to be kept until used. Sterilized milk is milk that has been heated at the temperature of boiling water or higher, for a length of time sufficient to kill all organisms present.

Effects of Heating.—Changes produced in milk by the application of heat depend upon the degree of heat and length of exposure. When exposed to a temperature of 140° F. for a short time it is not appreciably affected, either physically, chemically, or biologically, whereas when boiled marked changes are produced. As the result of boiling, certain changes occur in the taste and odor of milk, coagulation occurs at high temperatures, and it becomes discolored. There is a partial disarrangement of the normal emulsion and a coalescence of some of the fat globules, causing an increase in the viscosity of the liquid in which it is emulsified. Owing to this condition the cream does not rise well. Chemically, milk consists chiefly of water and, in additon, fat, lactose, several proteins, mineral salts, and certain dissolved gases. Heating to high temperatures causes a film or pellicle to form on the surface, consisting of fatty and protein matter. A precipitation of calcium salts takes place, thereby rendering the milk very acid.

Biologically, another change brought about in milk by the action of heat above certain temperatures is the destruction of enzymes, which are normally present in fresh milk. In reaching conclusions as to the temperature at which milk should be heated and the time of exposure to such heat, we are guided by two dominant factors, viz., (1) the thermal death points of pathogenic bacteria, and (2) the ferments in milk. To eliminate danger, the first must be killed, and at the same time the second must not be materially affected. It has been abundantly shown by investigation that most of the ferments in milk can withstand a temperature of 140° F. for some time without material injury, while the tubercle bacillus and other specific micro-organisms found in milk are rendered harmless by heating to 140° F. for twenty minutes. So far as bacterial toxins are concerned, little is known. It is known, however, that they are readily affected by heat, certain ones being rendered almost inert at ordinary temperatures. Let it be granted that heat-resisting poisons are present in milk, we will also have to grant the raw product quite as toxic and probably more so. By its destructive action upon the contained bacteria, heat may prevent the further production of such substances. Although it is admitted that milk possesses a germicidal property and that such property is destroyed by heat, it is not considered a serious objection to the heating of milk, for the reason that this property is exhibited by milk only during the first few hours after it is drawn.

Relative Nutritive Values of Raw and Heated Milk.—There is some difference of opinion as to the effect of heat upon the nutritive and digestive qualities of milk. In answer to one of the chief objections to the use of heated milk, that the heating "devitalizes" it, authorities state that heating milk to 140° F. for twenty minutes does not seriously affect the enzymes; and that if it be granted that milk contains "life," it has lost the last vestige of it after twenty-four to forty-eight hours, especially when kept under such conditions that it contains myriads of bacteria. In the boiling of milk, proteins are considerably altered, coagulation of certain albuminoid constituents takes place, thereby rendering them more difficult of digestion. It is stated that there is quite a loss of utility in the milk as the result of heating at high temperatures, and further, that it has been observed by many medical practitioners that there is a very distinctly lowered vitality among infants

fed on boiled milk, the processes of absorption being delayed, and the quantity of milk required for the nourishment of the child being greater. It is generally agreed that the digestibility of the milk diminishes with cooking. But among authorities consulted, the prevailing view is that when milk is properly heated, there is little or no prejudicial influence exerted in this respect.

Nutritional Disturbances.—Heated milk has been accused of possessing the great disadvantage of inducing scurvy and rickets. That highly heated milk is a contributive factor in the etiology of scurvy is generally believed, but that low-temperature heating, as is now recommended, ever in itself induces scurvy is not conclusively proven. Although there have been cases of this disease reported by observers as due to heated milk, comparative observations upon large numbers of infants, under like conditions show that they flourish quite as well upon properly heated milk as upon raw milk.

In Germany and France, where artificial feeding of infants with heated milk is most popular, thousands of children have been raised on heated milk, without the production of the disease. At all events the danger involved from the use of properly heated milk, with respect to the production of scurvy is so small in comparison with the advantages to be derived in other ways, that it may be disregarded.

Rickets is the result of defective alimentation and improper hygiene, and cannot be laid at the door of heated milk.

Acute Disorders of the Gastrointestinal Tract.—It is a well-established fact that the large majority of infantile deaths is caused by gastrointestinal disorders, resulting as it does in from one-third to one-half of all infant deaths under one year of age.

Investigation of infant mortality statistics reveals the significant fact that 75 to 85 per cent. of all infants who die of these diseases are artificially fed, and further that the vast majority of cases and deaths occur during the heated term. That this high mortality is unnecessary and may be greatly reduced by proper control of the milk supply is generally believed. While the factors involved are numerous, either primarily or secondarily, they depend upon the activity of microorganisms.

That it is best to use pure, fresh milk in artificially feeding an infant, all are agreed, but when the fact is considered that thousands of infants in our large cities are dependent upon the milk of a cow many miles away, a difficulty not readily overcome confronts us. Bad milk, heated or unheated, is unfit for infant feeding, but if infants must depend upon dirty, stale, bacteria-laden milk, it would be much better if properly heated, especially in the summer months, in spite of its alleged disadvantages. Freeman believes that the adoption of heated milk is by far the most important agent in reducing infant mortality from summer diarrhea. Park and Holt after observing groups of infants in the tenement houses and institutions of New York City, for periods of about three months in the summers of two years, concluded that those infants who received milk previously heated did on the average much better in warm weather than those who received milk raw. They state further that the difference was so quickly manifest and so marked that there could be no mistaking the meaning of the results.

Summary.—In making a comparative study of cow's milk, the intention of the writer is to point out and correlate from the vast amount of literature published in the past few years, facts of interest to the practitioner, in the consideration of sanitary milk in its relation to the public health, and the relative merits of raw and heated milk in infant feeding. That there are two sides to the question of heating milk, may be judged from the fact that conclusions of those who have given the matter careful consideration are diametrically opposed. Infants should receive breast milk, but when this is not possible, they should have the best cow's milk that can be obtained.

Whether such milk is to be heated or used in the raw state will vary with circumstances. In obtaining a general milk supply which is clean, fresh, and safe there is involved not only an expensive system of inspection and surveillance from the farm to the consumer, but there is required an intelligence and a high degree of technical skill on the part of the producer and all others handling the milk. Of an inspection so thorough and constant as to prevent milk occasionally becoming contaminated with the organisms of infectious disease, we can hardly conceive.

One of the chief objections to heating milk is that it promotes carelessness and discourages efforts to produce clean milk; that it will cause the producers and those who handle it to believe that it is unnecessary to be so particular. It is not proposed that the heating of milk shall take the place of inspection and improvements in dairy methods. Much has been said concerning the relation of scurvy and rickets to heated milk. This is still a disputed question, but, quoting Rosenau, "the evidence seems clear that these two diseases bear no relation whatever to the proper heating of milk."

The curd produced by rennin coagulation in heated milk is softer, less tough, and more flocculent than that produced in raw milk. This is believed to be an advantage favoring the digestibility of heated milk. Heated milk is said to be constipating. This is because it contains fewer bacteria than raw milk, and is therefore less irritating. While the danger of tuberculous infection through milk from diseased cows may be largely eliminated by the compulsory application of the tuberculin test, this expedient does not safeguard against possible tuberculous infection when handled by persons suffering with tuberculosis, or when kept amid surroundings frequented by tuberculous patients. Nor does it protect it from the organisms of typhoid fever, diphtheria, and other infectious diseases introduced into milk by a carrier, or through contamination in other ways in its handling from time of milking to time of consumption.

No less an authority than Theobald Smith expressed the opinion a few years ago that pasteurization was the inevitable outcome of the future. The heating must be done intelligently and be properly supervised. After heating, the milk is just as liable to serious contamination as before, if not more so, and therefore must be carefully guarded and kept cool. When all is said, it will be found that the objections raised to the proper heating of milk seem to be either theoretical or such as may be readily overcome. The writer feels no hesitancy in taking the view that the only practicable solution of the problem of obtaining milk in its least objectionable state at the present time appears to be proper heating. Theoretically, it should not be necessary; practically, we find it forced upon us.

THE PHARYNGEAL TONSIL IN THE ADULT.

BY LOUIS G. KAEMPFER, B.S., M.D.,

NEW YORK.

ASSISTANT IN DISEASES OF THE EAR, NOSE, AND THROAT, MT. SINAI HOSPITAL, O.P.D.

THAT part of the lymphatic infiltration of the mucous membrane at the entrance to the gastrointestinal and respiratory tracts which is situated at the roof of the pharynx—the pharyngeal tonsil—is greatest at the midline of the pharyngeal vault and differs from the faucial tonsil in that it has no definite limits but spreads out laterally to a greater or less extent. Some of its outlying parts may reach as far as the fossæ of Rosenmüller or spread into the openings of the Eustachian tubes. In these situations they become of special pathological significance.

The first signs of a pharyngeal tonsil can be detected in the later months of fetal life as small depressions in the mucous membrane, which later deepen and lengthen to form the crypts and become surrounded by the lymphatic cells. The greatest development of the organ is seen in the early years of childhood. After the fifteenth year there is retrogression of greater or lesser degree and in some old people no trace of the organ can be found.

Schwabach[1] has described the appearance of the pharyngeal tonsil in great detail. There are a series of anteroposterior grooves on the surface, which extend into the depths of the organ. There is a transverse anterior comb of adenoid tissue. The grooves are confluent posteriorly and some times anteriorly. There are also, usually, transverse grooves, less prominent than the sagittal ones, which go to form the anterior comb of tissue. When retrogression begins these grooves all become shallower and disappear. Often small cysts are formed. The median groove, being the deepest, is the last to disappear and cyst formation there is most common. The cyst formed from the median groove has been erroneously identified by a number of observers with the embryonic pharyngeal bursa first described in 1840 by F. J. C. Mayer.[2] Tornwaldt[3] showed the true nature of this almost constant structure. The infection of this pseudobursa and its distention with pus is the condition which bears his name—Tornwaldt's disease.

The term "adenoid vegetation" used to describe the hypertrophied or diseased pharyngeal tonsil is an unfortunate one, unless we will remember that it is not a peculiar sort of new growth of lymphatic origin, but an organ present in all, hypertrophied in most and diseased in a great many.

The pharyngeal tonsil is considered by most practitioners as a condition confined exclusively to childhood. That this is true in the greater number of instances is not to be gainsaid, but there are a sufficient number of chronic and subacute diseases of the upper air passages which can be laid directly at the door of the hypertrophied or diseased pharyngeal tonsil and the primary and significant cause of which goes unrecognized. These are the patients who have their turbinates removed, their nasal septa straightened, their ears politzerized for years, and their hypertrophic, and later when the nasal cavities have become lined throughout with scar tissue their atrophic rhinitis treated without relief. Should they finally escape infection of one or more of the nasal accessory sinuses they are to be considered as among the more fortunate of their class.

The symptoms of hypertrophied pharyngeal tonsils can be divided into two general categories—those referable to the presence of the growth such as mouth breathing with its accompanying local and constitutional changes, and catarrhal conditions of the nose, pharynx, and ears, and the anatomical changes resulting therefrom; and further, the secondary symptoms, such as swelling of the lymph glands of the neck.

Gradenigo[4] goes into the matter of mouth breathing and its effects at some length. In the question under consideration this phase does not concern us greatly, inasmuch as the effects of mouth breathing and the changes induced take place in the earlier years and by the time the patient reaches adult life the removal of a hypertrophied tonsil will not restore him to a normal condition.

Among the most important of the permanent local changes resulting from mouth breathing and which follow the patient into adult life, even after nasal breathing has been re-established by the removal of the hypertrophied tonsil or its retrogressive shrinking, are a high arched palate with its narrow alveolar arch, and crowding and faulty alignment of the teeth. There is always, in these patients, more tendency to caries than when the teeth have sufficient room and wider interstices where chemical changes between the saliva and food débris can be prevented.

Again, the high arched palate of this type is usually accompanied by a deviation of the nasal septum and a narrowing of the entire cavity of the nose. Robert, cited by Gradenigo[4] says that the smallness of the nasal cavity as a whole is due to the fact that the nose, in children who are mouth breathers, is not used and that, therefore, there is nothing making for the development of this portion of the breathing apparatus. This smallness persists after the bones have become calcified; in other words—an atrophy of disuse.

There is, however, a group of cases, and the number is not small, in which the etiological factor is a diseased pharyngeal tonsil and in which the symptoms are due to the mild degree of chronic inflammation of the contiguous mucous membrane of the nasopharynx and nose with hypertrophic changes in the mucous membrane and increase of secretion. This may result in hypertrophy of both the middle and lower turbinate bodies to any degree of severity.

Many of these cases give no history of "adenoids" in childhood and show none of the stigmata one would expect to find in chronic mouth breathers. They are the patients, whose pharyngeal tonsils, never very large, have left the choanæ free and did not interfere with respiration. The tonsils do not retrogress but persist into adult life with open crypts as unconsidered sources of infection. These patients are benefited and their symptoms ameliorated by the removal of their pharyngeal tonsils. Even when there are hypertrophied turbinates and septal spurs the removal of the diseased pharyngeal tonsils and the abatement of the chronic rhinitis causes a shrinking of the mucous membrane and

gives the patient sufficient space for normal nasal respiration.

The posterior pharyngeal wall in these cases is studded with small masses of lymphatic tissue giving it a granular appearance. To this condition the name granular pharyngitis has been given. Certain cases of pharyngitis sicca in which there is no involvement of the nasal accessory sinuses are relieved by ablation of the pharyngeal tonsil.

The relationship between the hypertrophied and diseased pharyngeal tonsil and the ears has been carefully studied by a host of competent observers. The rapid amelioration of the discharge and the final closure of the perforation in chronic purulent otorrhea of childhood following the removal of the pharyngeal tonsil is a familiar occurrence. When the inflammatory process extends into the Eustachian tube and middle ear there is a gradual diminution in the acuteness of hearing which may end in complete deafness.

In each act of swallowing air is forced through the Eustachian tube into the tympanum to maintain equal pressure on both sides of the drum membrane. With the swelling of the mucous membranes of the Eustachian tube this becomes progressively more difficult of accomplishment and less and less air is sent through at each charge. The air pressure within the tympanum is lowered and the drum head forced inward.

In these early cases when there is simply mechanical obstruction, the hearing can be restored to a degree by insufflation of air after the manner of Politzer or better by the gradual distention of the lumen of the tube by means of woven silk bougies. Later when permanent changes have taken place in the living membrane of the tympanum with the formation of adhesions between the vesicles and the tympanic walls and the possible involvement of the bony walls themselves the hearing is permanently injured. Gradenigo[4] says that he has found catarrhal otitis much oftener accompanied by hyperplasia of the pharyngeal tonsil than purulent otitis.

The orifice of the lacrymal duct opens under the inferior turbinate in a position where, apparently, inflammatory processes in the nose can affect the outflow of tears and produce a stricture similar to that of the eustachian tube under like circumstances. The condition of the nose is an important factor in the treatment of obstructions in the lacrymal canal. At the present time, when the intranasal operation for lacrymal duct obstruction is coming into favor the presence or absence of intranasal inflammation may determine the success of the procedure.

The diagnosis of hypertrophied or diseased pharyngeal tonsils in the adult presents no difficulties if one will but look for them. The classical picture of childhood is, of course, not present. If a patient with symptoms of some chronic catarrhal process of the nose, nasopharynx, or ears has a large or a diseased pharyngeal tonsil one can say with a fair degree of probability that the presence of this pharyngeal tonsil bears an etiological relation to the inflammatory process and its removal will result in a cure or in relief of the symptoms.

There has been little in recent literature covering the effect of hypertrophy in disease of the pharyngeal tonsil on the adult. Barstow[5] in 1905 reported fifty-seven cases of persons between the ages of twenty and forty-two on whom adenectomy was done with favorable results. There was improvement in all and complete relief in most. Of these thirty-six were throat lesions, chronic pharyngitis in most instances, and twenty-four were ear cases. In a number of cases with enlarged turbinates there was complete relief after adenectomy.

During the past few months the writer has performed adenectomy on a number of adult patients with favorable results. Of these six cases will prove of special interest. Five of the patients were women. The youngest was eighteen, two were twenty, one twenty-three, one twenty-six, and one thirty-two. Two had hypertrophied lower turbinates with thick, congested mucous membrane, two had enlarged middle turbinates with deviated septa and septal spurs, one had a chronic catarrhal otitis with stricture of the Eustachian tube, and one had a chronic purulent otorrhea.

The two patients with enlarged lower turbinates were very promptly improved by operation. They no longer complained of feeling of fullness in the nose. Their profuse secretion of nasal mucus became less, and the turbinates appeared smaller and less congested.

Of the two deviated septa, one was improved. The other patient had a marked deviation with large bony ridges. Both middle and inferior turbinates were hypertrophied, the mucous membrane was thick and red and there was a profuse discharge of clear, watery mucus. After adenectomy the congestion became less and the amount of discharge diminished, but there was little relief from the feeling of fullness and the obstruction to respiration.

The chronic purulent otorrhea was of about eight years standing and had been treated from time to time without results. The patient was an underdeveloped girl of eighteen. She had been backward at school and her family described her as "dull." She was a chronic mouth breather. During the six months following the removal of a large diseased pharyngeal tonsil the girl developed in a remarkable manner. Before operation she had had the physique of a child of fourteen. She grew taller, gained in weight and became as any other girl of her years, in appearance. The ear discharge diminished but did not entirely disappear. It still had the odor of an infection coming from the oral cavity. The outer attic wall was removed together with the ossicles and the Eustachian tube curetted. This was not successful and after some weeks the tube was found to be still patent. A second curettage had a more satisfactory outcome. The discharge became less and lost its foul odor, and at this time the patient remains under treatment with only a slight amount of discharge, which is slowly diminishing.

The other ear case in this series a chronic catarrhal otitis media with Eustachian catarrh, also of eight years' duration, was in a woman of thirty-two. For seven years it had gone untreated. Then she had been treated for almost a year by repeated politzerization, without relief. Portions of her turbinates had been removed, also without improvement. After adenectomy her hearing, under politzerization, improved slightly, but after a time went back. There was more improvement after dilatation of her Eustachian tube and during treatment of her chronic pharyngeal catarrah, but the patient passed from observation before anything definite could be determined. These results coincide with those of Barstow.

As a result of careful observation in this class of

cases the writer offers the following conclusions:

1. The pharyngeal tonsil persists into adult life, sometimes entirely unchanged, anatomically.

2. It acts in those cases as the causative or, at any rate, as an important contributory factor in some of the stubborn chronic conditions of the nose, pharynx, and ears of early adult life.

3. It should be the duty of the rhinologist to determine, as part of his routine examination, whether or not a diseased tonsil of this kind is present and whether its removal will not save the patient from more radical operative interference or obviate a long course of more or less painful treatment.

A CASE OF AURICULAR FLUTTER OCCURRING DURING RHEUMATIC ENDOCARDITIS.

BY SELIAN NEUHOF, M.D.,

NEW YORK,

VISITING PHYSICIAN, HAR MORIAH HOSPITAL; ADJUNCT ATTENDING PHYSICIAN, LEBANON HOSPITAL.

M. D., female, aged 35, unmarried, entered the hospital with the history of many attacks of acute articular rheumatism and of having had "heart trouble" for many years. She frequently complained of dyspnea and palpitation. Her present illness began with chills, fever, and swelling and redness of both knees. Her physician stated that the pulse had always been regular during this illness. The patient looked wan and anemic; she was dyspneic; there was a productive cough, but the sputum contained no tubercle bacilli. Physical examination revealed the signs of general bronchitis and of a double pneumonia at both bases posteriorly. There was a strong heaving precordial impulse accompanied by a palpable systolic thrill. The apex beat was most marked in the sixth interspace, fifteen centimeters from the midsternal line; on percussion the right border was ten centimeters from the same line at the fourth interspace. On auscultation there was a loud rough systolic murmur heard best at the apex and a softer murmur occupying the entire diastole. The diagnosis of a double mitral lesion was made. From the configuration of the left cardiac border to percussion and the presence of pericardial friction sounds, the probable diagnosis of pericarditis with effusion was also made. The temperature ranged between 101° tnd 103°. For two days the pulse remained regular, the rate between 110 and 120. There then occurred a sudden drop of the ventricular rate to 40 per minute; from that time till death, three days later, it varied between 30 and 55. At the high rate it was sometimes regular for a minute or two, then the rhythm was suddenly interrupted by much slower beats. A distant rumble occupied the entire longer diastolic pauses. From the inception of the slow rhythm, there was an enormous dilatation of the jugular veins, so that the sides of the neck literally swelled with the frequent and vigorous venous pulsations. There were no convulsions. The dyspnea, fever, cough, and slow pulse continued until death occurred. A blood culture taken a few days before death remained sterile. An autopsy could not be obtained.

Polygraphic Tracings.—For comparison a normal tracing is shown in Fig. 1; *R* represents the radial pulse; in the jugular tracing are seen the sequential waves *a-c-v*, in which *a* represents the auricular, *c* the carotid, and *v* the ventricular filling wave. Fig. 2 (*a*, *b*, *c*) and Fig. 3 (*a*, *b*, *c*) were obtained on different days, the lettered sections are continuous. Their characteristic feature is the regular, rapid auricular rhythm, representing auricular activity at rates of 210 and 245 per minute. Regular auricular rhythm at such rates is called auricular flutter. Many of the auricular beats are not answered by ventricular contractions, an evidence of heart block. In some parts of the tracing, for example, in Fig. 2 (*c*), there is for a time a rhythmic ventricular response to every fourth auricular beat, an evidence of partial heart block with a 4:1 rhythm. Apparent partial block is also seen in Fig. 3 (*b*), at I, but the other beats show complete block, though there is no marked difference of ventricular rate in the immediately preceding or succeeding contractions. The radial rate varied from 25 to 50 per minute in different parts of the tracing. Lewis[3] states that auricular flutter is usually accompanied by partial heart block and that an irregular radial pulse, when present, is due to varying ratios of ventricular response to the auricular beats. He has proved this by measuring the arythmic groups of radial beats which, when added, are found to be exact multiples of the auricular contractions. Such ratios are not found in our tracings, so that unless sudden, irregular interruptions of the normal *a-c* conduction time is assumed—an extremely improbable anomaly—the heart block must be regarded as of two types, complete and incomplete. Of interest in the radial tracings is the fact that, except in that part of Fig. 2 (*c*) which follows the extrasystole *v'*,

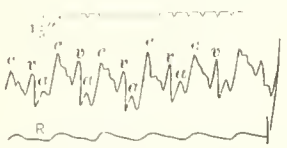

FIG. 1. Normal Polygraphic Tracing. *r* = radial beats, *a-c-v* = rhythmic jugular waves. The time marked in all tracings indicates 1 5 second.

the slow beats are lower in amplitude than the more rapid ones. This represents weakened ventricular contractility as compared with the latter, and may be due to the fact that the lengthened diastole and consequent extreme ventricular filling has imposed upon the diseased left ventricle a task which it cannot properly perform.

Discussion.—Up to October, 1913, thirty cases of auricular flutter had been reported.[2] Mackenzie[1] reports thirty others. Two have been reported in American literature.[4] Lewis[3] has described definite electrocardiographic characteristics of this condition. These and the comparative frequency of auricular flutter entitle it to be classed as a clinical entity. Most of the cases have occurred in elderly individuals with severe cardiac lesions. Mackenzie believes that the underlying pathological condition is probably an auricular fibrosis producing local irritation, though it may also be due to acute cardiac infection, an example of which he gives (p. 435). Ritchie[5] describes the autopsy of a man, thirty-seven years old, who suffered from endocarditis and decompensation and who developed auricular flutter for one day, ten days before death; the ventricular rate was 160, the auricular, 320 per minute. The pathological findings were slight, diffuse, inflammatory myocarditis with slight invalvement of both nodes, the *a-v* bundle and its branches, endocarditis of the mitral and tricuspid valves and acute pericarditis implicating the sino-auricular node. Gibson[6] reports a case in whom auricular flutter was

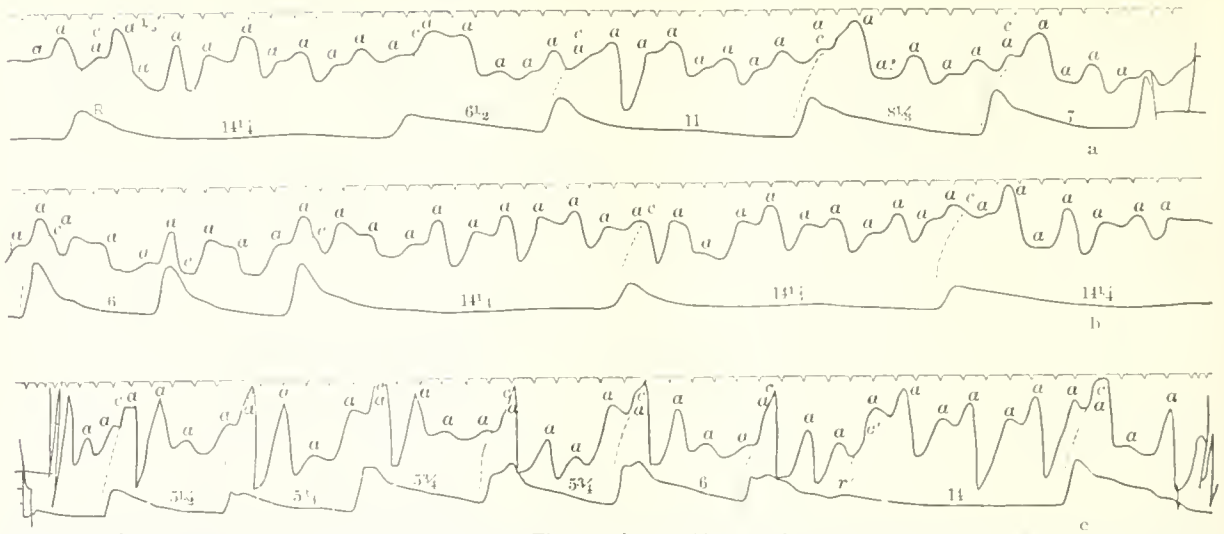

Fig. 2. *a, b, c* are sections of continuous tracings. The regular rapid auricular rate is shown by the *a* waves, a few of which are deformed by the respiration. *R* = radial pulse, *r'* = extrasystoles. The incidence of the carotid wave (*c*) in the jugular tracing is indicated by the dotted lines. The numbers on the radial curves show the lengths of the radial beats in fifth seconds. The auricular rate is 210 per minute. Block is complete in Fig. *a*, *a* and *b*; it is partial in part of Fig. 2, *c*.

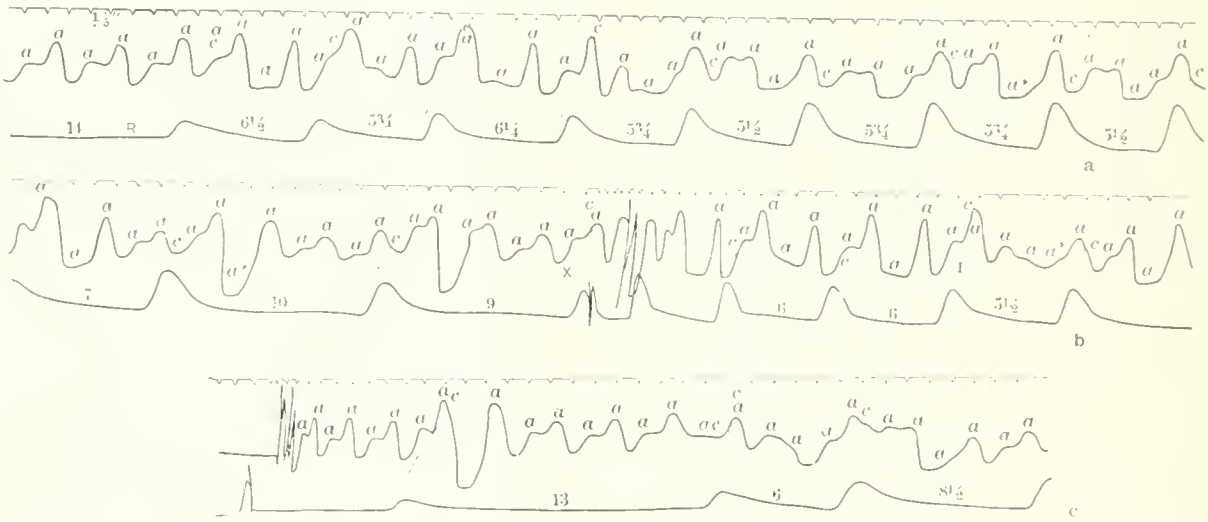

Fig. 3. *a, b, c* letters indicate same as Fig. 2. The auricular rate is 245 per minute.

found upon one occasion; the postmortem showed increase of fibrous tissue, and cellular infiltration of the *a-v* bundle. In our case, the rheumatism, pneumonia, endocarditis, and pericarditis were probably evidences of a rheumatic reinfection. The inception of the auricular flutter was not accompanied by inferential symptoms of a cardiac infarct, there was no sudden or sharp angina, no increased dyspnea; and it is quite problematical whether such an accident would cause rapid, regular, auricular activity. The history and clinical course of the case make it probable that the flutter was the result of a terminal infection involving all cardiac structures—pericardium, myocardium, and endocardium, and was not confined alone to the specific cardiac structures—the sinoauricular node and the auricular ventricular connections.

Summary.—A case of auricular flutter with varying periods of complete and incomplete block is described. It occurred in the course of a severe recurrence of a rheumatic endocarditis and appeared to be the result of a terminal infection involving all the cardiac structures.

I am indebted to Dr. J. Kaufmann, Visiting Physician to the German Hospital, for permission to report this case.

MODIFIED AND CONSERVATIVE RADICAL MASTOID OPERATIONS FOR TOLERANCE OF PROSTHESES IN CASES OF DIMINISHED HEARING AFTER MIDDLE-EAR SUPPURATION.

By W. SOHIER BRYANT, A.M., M.D., F.A.C.S.,

NEW YORK.

Among cases of residual deafness, following middle-ear suppuration, including both those cases that have undergone any form of operation and those that have undergone none, there is a large number in which the hearing is very considerably increased by the use of suitable prostheses. Among these last, there are some cases in which the ears,

although they may be quiet and dry, and have no suppuration, begin to suppurate as soon as a prosthesis is applied. This class of ear is characterized by the presence of crevices harboring desquamated epithelial, cicatricial folds, trabeculæ, and ossicular remnants about the middle ear and mastoid antrum.

In these cases we have found that a modified radical mastoid operation or a so-called conservative radical mastoid operation is indicated. The intention in these operations is twofold: first, the hearing mechanism is to be preserved in as good condition as it is previous to the operation; and second, the middle ear and accessory cavities are to be cleaned so that the middle ear will heal in a smooth, readily epidermatized, clean cavity and will consequently tolerate a prosthesis.

The technique used in these operations is adapted of course to the condition present. In the conservative radical mastoid operation the auricle is deflected forward, together with the membranous canal, in the way preferred for the radical mastoid operation. The posterior and superior walls of the osseous meatus are removed, exposing the attic, the antrum, and the middle ear precisely as in the radical mastoid operation.

The middle ear is carefully freed from obstructions, such as remnants of the major ossicles, cicatricial bands, or walls of trabeculæ. Care is taken not to remove the dermoid covering of any structure that is not also to be removed; that is, unnecessary denudation of the middle ear should be avoided. After the middle ear has been carefully freed of the unnecessary contents, the membranous canal and concha are treated plastically, to insure an enlargement of the external meatus, in proportion to the enlarged osseous meatus. The modified radical operation follows the same technic as the preceding except that the major ossicles may be retained in position. After these operations the ear usually heals rapidly and gives very satisfactory results in hearing by the tolerance of a prosthesis. The following case illustrates the practical value of these operations:

A woman, 33 years of age, was dependent for all her hearing on a chronic suppurating ear. Without a prosthesis the Politzer acoumeter was heard at 7 inches; with the prosthesis in position, the acoumeter was heard at 25 inches.

The suppuration ceased soon after the cleansing treatment was commenced. The Politzer acoumeter was then heard at 6 inches without the prosthesis and at 23 inches with the prosthesis. Soon, after a continuous use of the prosthesis, the suppuration recurred, but was easily controlled. This procedure was repeated several times and always with the same result. It was then decided that a modified radical mastoid operation would be performed on the ear in order to preserve what hearing remained, and, at the same time, make the ear tolerant of a prosthesis.

The condition of the middle ear was as follows: the membrana tympani had largely disappeared and the remnants of the ossicles were bound in a cicatrix in the posterior region of the tympanic cavity. Since the hearing was very satisfactory with a prosthesis in position, it was decided not to risk any impairment of the hearing by interfering with the contents of the tympanic cavity. The antrum was opened widely into the tympanic space and canal, and this was sufficient to assure cleanliness enough to allow the continuous use of the prosthesis.

The operation followed the technique of the ordinary radical mastoid operation, as far as the management of the membranous and osseous meatus was concerned. Nothing in the tympanic cavity was removed and great care was exercised not to disturb the remnants of the malleus and stapes, which was all that remained of the ossicular chain.

The wound healed by first intention and in a few days the ear and canal were dry and desquamating. Two years after the operation the Politzer acoumeter was heard at 15 inches without the prosthesis, and at 96 inches with the prosthesis in position.

In a second case, similar to the previous one, it was thought best to remove the remnant of the major ossicles, and therefore a conservative radical mastoid operation was performed. In this case, the operation included the removal of the remnants of the malleus and incus and part of the head and crura of the stapes. The results were quickly obtained and were as satisfactory as in the first case.

MENTAL AND NERVOUS MANIFESTATIONS OF PELLAGRA.

By THOMPSON FRAZER, M.S., M.D

ASHEVILLE, N. C.

The prominent part played by the nervous system in the symptomatology of pellagra is well known; the acute neurasthenic symptoms which characterize the outbreak as well as the various psychoses met with at other stages are familiar to all. Pellagra, however, follows no set copy and the symptoms which occur in the course of the disease are so varied, so inconstant, that unless one be on the lookout for them they may quite readily escape detection. To one unfamiliar with the disease the symptoms are but shifting sands; but he who has learned to recognize the many-colored picture of pellagra sees a warning in the most wanton of symptoms. And while it is true that in the earlier stages the patient is comparatively free from symptoms between attacks, these become more numerous and more constant as the disease progresses so that the clinical picture may resemble that of a severe neurasthenia. With the psychoses I shall not deal, my paper being based on a study of pellagrins who have applied for treatment on account of digestive disturbances, dermatitis, or "nervousness." While the protean character of pellagra is almost a by-word, the variegated patterns exhibited would surprise the most imaginative. For, while the symptoms—and pellagra is literally *blessed* with symptoms—are conveniently grouped under the headings "skin," "nervous," "digestive," etc., the disease is not cast in any one mould; it seldom "breeds true," as the biologists say, and it is essential to learn to recognize the various disguises which it at times assumes.

One dare not, of course, make a diagnosis on a stray symptom but when a series of apparently unrelated complaints are deliberated upon, there is discovered a symptom-complex which spells pellagra. In considering the nervous symptoms of this disease I have thought it best, where possible, to let the pellagrin speak for himself, presenting his case in the graphic and often inimitable speech of the mountains. Evidence thus submitted has a distinctive flavor, a touch of reality not otherwise obtainable.

Sensory symptoms are extremely common and make up the bulk of the pellagrin's complaint. *Pain* of some sort is usually the major grievance. Most patients have had at some time a pain, or an ache,

or a "misery," or a "hurting," for which they sought relief. The most usual location of the pain is in the back. This may be dull in character, or of transient duration, it may vary greatly in intensity from day to day: it is quite often so severe and so constant that it makes life miserable. In a fair number of cases the pains are referred to the hips, or to the hips and thighs. The complaint is made that the "joints tingle." Pain in the legs and in the feet I consider a valuable diagnostic hint. The pain in the feet is sometimes described as numbness, very often, however, the pain is of a burning character, worse at night, and so severe that it interferes with sleep. One woman said that it was the most annoying of all her symptoms, if she "could just get shet of that" she wouldn't care what happened. It was associated with paresthesia on the top of the head, a spot on the scalp that "might be hot, might be cold." One old man said his heels felt "as if in hot ashes." Sleep was well-nigh impossible. The pains and paresthesiæ in the legs include formication, a sense of constriction, and a "drawing of the leg," cramp-like in character. The latter is by far the most severe and, like the burning pain, is worse at night, preventing sleep and increasing exhaustion. These cramps, or "drawings," or "jerkings," when present, always loom large among the pellagrin's complaints.

A word must be said about pains in other parts of the body though I have not found them as frequent a source of complaint as those located in the back, feet, and legs. Cramps, however, may take place in the muscles of the arms, in the abdomen as well; while flitting pains in various parts of the body are extremely common. Quite often they are located by the patient between the shoulders or under the shoulder-blades and are described as burning, tingling, and "hot and cold spots." Various other paresthesiæ, seemingly erratic in their locations, are met with. One very nervous woman's word picture of her sensations was "a jarring of the joints"; and her elbows felt "as if they were in a pan of water." General soreness I have noted in only a few instances.

Headache, not usually considered as a prominent symptom, I have found pretty frequently, more especially in the early pellagrous career. It does not seem to be a very annoying symptom and may not be elicited unless the direct question is put. Other sensations referred to the head and usually described as noises, are quite common; such are: "a throbbing in the ears" and "a roaring and a ringing." "My head sings," said one, in the expressive idiom of the mountains. A sense of lightness in the head varying from that which makes the patient "feel foolish" to a more marked and persistent vertigo, is a common associate of the noises referred to; in one case fainting-spells occurred in which the patient became "dead as a hammer."

The list of sensory symptoms might be almost indefinitely extended; I have attempted only a selection of the most common ones. When considering the occasional symptom one wonders whether it be due to pellagra or to some other cause, thus, aching eyeballs I have noted in but one case, deafness in two, both of which were old men.

Before leaving the subject of the sensory symptoms it should be noted that frequently *stiffness* rather than pain is complained of—stiffness of the muscles of the back and of the lower extremities, so that stooping over is performed with difficulty, rising and sitting down are laborious, and the gait is awkward, rigid. With this stiffness there is actual weakness of the muscles of the back and of the lower extremities; as the pellagrin says: "My strength is good in the arms and shoulders but my legs give in." General lassitude and physical weakness, as well as contractures of the leg muscles all contribute to make the gait slow and inelastic. Contractures of the toes, and of the little and ring-fingers are sometimes seen.

A tremor, made worse by exertion, is not infrequent. "As soon as I do anything I get all in a quiver" was the comment of one pellagrin, while another in equally good Appalachian said that he could not do "ary a lick of work without getting all a-tremble in a few minutes."

It need hardly be said that insomnia is one of the most distressing symptoms of pellagra. All degrees of sleeplessness are met with. "I sleep after midnight" one hears from those who suffer with it in its attenuated form. "I toss all night" is the complaint in the severe cases. Sleeplessness, in some, seems to be a part of the general neurasthenic condition, while others are unable to sleep on account of the burning pains in the feet, the cramps in the legs and other parts of the body. A sense of vertigo on closing the eyes is experienced by some. "I have to open my eyes at night because things tremble—like I'd had too much to drink," confided one. This sensation lasts several hours.

Adding to the exhausted condition of the patient as it does, the importance of the symptom, insomnia, cannot be overestimated. I might say with regard to the reflexes that I have not derived much information from the knee-jerks. Usually increased during an attack, I have found them quite variable—increased, normal, decreased—in the interim, so that as a diagnostic sign they are not reliable.

Having considered the "nervous" signs of pellagra and turning now to the "mental" aspect of the disease (although the demarcation is one of convenience only), we note such a host of symptoms that in this brief paper it is possible to allude to a few only, of the more common. It is not necessary here to consider the mental symptoms of the attack as they are so well known; the lassitude, depression and anxiety are short-lived, and with the recession of the attack what might be called the "acute neurasthenia" gives way to the usual psychic condition. And, in many cases there may be no mental symptoms discernible between attacks. After several attacks, and with the advance of the disease, we shall commonly find symptoms if we seek them. While the convenient, the abused, and the all-inclusive term "neurasthenia" might be made to cover the symptoms about to be enumerated, their scope and variety would seem to warrant further particularization.

Thinking, feeling and doing are all affected and it may be convenient to consider the symptoms as related to the receptive, emotional, and purposive aspects of the mind.

With the progress of the disease the pellagrin takes less and less interest in his surroundings: he is unresponsive to the usual stimuli, he may not answer when spoken to. This unconcern is often shown in the facial expression which is so set as to amount almost to an entire absence of expression. One woman of rather better than average mental endowment noted that during the last few months she seldom *thought*—she was content sim-

ply to "set and stare." Inattention is due in part at least to the mental preoccupation of the pellagrin; the strange sensations which he wonders at and seeks to interpret direct his attention inward and he becomes morbid, self-centered and indifferent to his environment. Some give unfeeling, monosyllabic replies to all questions, others, conscious of being "not right in the head" give with great detail their various impressions. Owing to introspection it takes some time for sensations to break in upon the pellagrous mind so that thought processes are delayed and memory much impaired. Things, events don't seem real,—but "as if there were a veil over the mind."

Turning to the emotional aspect of the mind we note a great instability as the disease progresses. The pellagrin is irritable, lacks patience, self-control. One woman remarked that she cried without the slightest reason. Another said: "The least thing gets me in an uproar." Still another, in the patois of these purlieus: "Hit seems like I'd go plumb crazy if I was confined to set still for ten minutes." The unaccustomed sensations, at first a source of surprise and wonder, soon lead to anxiety, to apprehensiveness; the pellagrin worries over trifles and the consciousness of this unwisdom increases his mental embarrassment. The emotional state is apt to be mercurial in its instability; up one day, down the next. At times a curious mixture of anxiety and indifference may be noted: the patient analyzes his mental processes in a neutral, dispassionate manner, as if belonging to another person. Fear and hope are often strangely blended; the pellagrin attempts to offset his "queerness" by keeping "in good heart", and the fortitude exhibited by these sufferers in spite of their mental and physical ills, is most remarkable. Fear, however, conquers sooner or later, or gives way to despair, which is reflected in the apathetic manner and the sad, set face so often noted.

We have next to consider the mental state in its bearings on the will, the conduct of the pellagrin. It need hardly be said that activity—mental and physical—becomes hampered; the pellagrin has to "stand and study a bit" before doing some usual, every-day act. As he takes in little, he gives out little. His endurance becomes affected and a ready fatigability still further cripples his activities. One patient noted early in the course of the disease that he could not write a letter without making a dozen mistakes. Muscular weakness adds to the physical inactivity: ordinary movements are performed slowly and with difficulty.

The changes in the mind keep pace with those in the muscles. There is real mental torpor: the will-to-do is soft-pedalled and ambition languishes. The general air of apathy, of lack of spontaneity, the aged face, with wrinkled brow and expressionless features, the lifeless monotone of the voice, are all evidence that psychic processes have reached a low ebb.

Such, then, are a few of the nervous symptoms of pellagra which pass before us in motley procession. I have preferred to review them thus briefly rather than to attempt to define a particular type, or types of cases. I do not wish to intimate that the symptoms described are all present at any one time or in any given case, for to do so were misleading; it is the multiplicity of symptoms, and their banditti-like appearance and disappearance which contribute to the make-up of that kaleidoscopic pattern of disease that we call pellagra. While the individual sympton may be with difficulty ascribed its proper cause, the complex of insomnia, vertigo, stiff back and burning feet is almost too characteristic to leave one in doubt; and (especially if associated with other symptoms such as loss of weight, pyrosis, or diarrhea), should enable one to arrive at a proper solution, or to go as far as one may dare, go without the absolute evidence of the symmetrical dermatitis.

THE PHYSIOLOGY OF ABDERHALDEN'S TEST AND ITS VALUE IN THE DETERMINATION OF PREGNANCY, WITH A TABLE OF NINETY CASES.*

By KARL H. GOLDSTONE, M.D.,

BROOKLYN, N. Y.

Professor Schmorl of Dresden, in 1893, reported the existence of chorionic epithelium in the circulating blood of the pulmonary arteries in eclamptics. J. Veit of Halle, in 1900[1] found chorionic villi and connective tissue also in the uterine veins. The latter is authority for the statement that R. Nitabuch, working with Langhans, saw them many years before, and that Breschet reported the same findings in 1826. Heilner[2] was the first to demonstrate the action of blood ferments on injected albumin. But it remained for Abderhalden (with Pincussohn and Weichardt)[3] to put this on a working basis. Prof. Abderhalden then began his work on the serobiological determination of pregnancy,[4] taking into account the proven physiological fact that ferments are formed by the blood in which they circulate when foreign substances are introduced. He cites the well-known physiological dogma that the intestinal canal, with its associated glands, produces ferments whose function it is to break up food elements in such a manner that none of the original food structure remains. To use his classical phrase, "Baustein wird von Baustein gelöst," meaning, every element in the food foundation is separated from its neighbor, until there remains but a collection of indifferent products, to be utilized later by the system. These serve the body cells in their manifold functions, and from these "indifferent products" the protoplasm and its nuclei build each after their own plan. The foregoing mentioned "breaking up" takes place in a step-like manner. The broken up products are at once resorbed and carried to the body cells. Besides this "breaking up" (which might be substituted by the terse German expression, Abbau), there also take place oxygenation and reduction, according to the needs of the cells. Likewise the intestinal canal is assisted by the liver, whose duty it is to hinder the entrance of foreign "stuffs" into the blood. Still other protective agents are the kidneys and probably the leucocytes.

So we are thus reminded of the well-known principles of physiology, namely, the action of external or gland ferments, secretions, excretions, and phagocytoses.

In the foregoing we had to do with the entrance of foreign material per os. But we are now occupied in a biological way with a variety of internal ferments, protective ferments, whose function it is to change and take over foreign matters that enter, not per os, but by the blood current, such as parenteral albumin, derived from the placenta.

*From the Royal University Hospital for Women, Kiel, Germany.

In order to recognize these parenteral and blood foreign bodies, we must make use of new methods, and here we are so concerned.

Abderhalden[3] set to work firstly to study the problem as to whether the blood plasma has the power to break up blood foreign material, and if the ferments so concerned could be isolated. The former problem he succeeded in proving; he also demonstrated the ability of the blood to break up fats. But most important were his studies as to the ability of the organism to break up parenteral substances of the albumin group—peptone, polypetide, protein, and amino acid. He also proved that these blood ferments not only broke up, but also naturalized alien bodies and turned them to account. These experiments raised numerous other questions, which I shall not enter into here. But sufficient it is to say that we have fully proven the existence of blood ferments, ferments whose function it is to break up albumin into assimilable elements, though these experiments have not advanced as far as to positively state their nature.

Abderhalden[4] set to account this foregoing dogma in the utilization of the now well-known serobiological test for pregnancy. This test is most discernable within the first six months of pregnancy. Even in the first few days of conception the reaction can be determined. This is especially of value in extrauterine pregnancy. After birth the reaction begins to disappear, being evident from eight to fourteen days in the puerperium. Investigations up to date have shown that these ferments are specific only against placental peptones.

It is interesting to note that in toxemias of pregnancy this Abbau of placental peptones does not occur in the usual way. One wins thus the impression that the blood of eclamptics is not able to form protective ferments. This is the basis of Veit's theory of eclampsia. Also in pregnant women dying from any cause whatsoever the "Abbau" is absent or lessened.

Further, allow serum from a normal pregnant woman plus serum from an eclamptic to act on a normal placenta. The dialysate injected into mice intraperitoneally produces no untoward effect. On the other hand, allow these sera to act on an eclamptic placenta, and the dialysate injected into mice causes profound toxic symptoms. Still further, heat the serum for ten minutes at 60° C.; then allow it to act on eclamptic placenta; again inject the dialysate and the mice remain well. By the warming process the proteolytic ferments are destroyed.

I shall not attempt in this paper to dwell on the pathological side of this question—namely, the ability of this test to detect morbid conditions. This is a subject in itself about which I will have more to say at some subsequent date. I have also omitted a description of the technique of Aberhalden's test, for at this late date I believe we are all more or less acquainted with its workings.

I will add only that the methods are two in number: (*a*) the dialyzing method and (*b*) the optic or polarization method. The former is the simpler and requires inexpensive apparatus. The latter is much more arduous and is expensive to operate, necessitating an especially constructed polariscope costing in Germany about $400.

The dialyzing method is not difficult, but it requires painstaking and exact labor.[7] The articles on the subject so far appearing in America would have it as "a very easily performed test requiring a few dialyzing membranes, test tubes, and pipettes." One can at once see the fallacy of these statements by taking into account the numerous late writings by Abderhalden himself, in which he devotes his whole energy to detailing the numerous errors that may be made in performing the test, pleading all the time for the observance of exactness and care. The test carelessly and not delicately performed gives absolutely no results.

The following is a list of ninety cases treated by the method of dialysis: The cases were taken at random and the blood was labeled in such a manner that I was not aware of their proprietorship until the completion of the tests. The amount of serum employed in all cases was 1 c.c., instead of the usual 1.5 c.c. This was done to avoid any reaction that might have ensued from protein-laden sera—that is, sera holding enough albumin to react with 0.02 grams of ninhydrin, as may occur from blood taken after a meal rich in proteins. The amount of placental mass employed was one-half gram, instead of one gram, with a similar purpose of minimizing the end (color) readings, in that way to detect the very smallest amount of Abbau. This may seem a paradox, but all observers have satisfied themselves that a positive reaction ensues in nearly 100 per cent. of certain pregnancies. It is only with the non-pregnant and pathological cases that the end results of the various workers are not in accord.

The latest reports on the use of Abderhalden's reaction in health and disease are by his co-workers at Halle, Lampe and Papazolu (of Budapest)[8]. These authors assert that not only species-foreign and body-foreign matter make mobile ferments in the blood, but also blood-foreign, lymph-foreign, and cell-foreign substances, and they can (by the action of these ferments) be converted into body property. The production of these ferments has for its purpose the naturalization of stuff foreign to the blood, lymph, and cells.

By these means we are thus able to function-prove all organs—that is, to diagnose biologically disfunction. If the tasks of these authors prove worthy then we can hope to obtain a deeper insight into the pathogenesis of disease. Their first experiments demonstrate that sera from organ-normal persons have absolutely no Abbau properties. The experiments of Lampe and Papazolu consisted of allowing sera from healthy persons to act on various organs, thymus, liver, pancreas, muscle, adrenals, ovary, testicle, and placenta. The dialysate is tested in the usual way with ninhydrin. These were mostly negatives (98 per cent.), which clearly shows that there are no active circulatory ferments in the blood of healthy individuals, for the very evident reason that "protectors" are unnecessary. To cast a further ray of light into the possibilities of this line of labor, one need only consult the extensive work of Fauser[9] who proved that sera from persons suffering from Basedow's disease had the power to break up thyroid gland tissue.

117–118	Salpingitis-appendicitis	−	Operated
101	Abdominal tumor	+	Later verified as positive pregnancy
76*	Pregnancy, 6 months	−	Wassermann positive
65–72–73–75			
77–79	Pregnancies from 5 months to full term	+ +	All verified by positive signs or advent of labor
80	Amenorrhea of 4 months duration	−	Later diagnosed as hæmatometria
81††	Extra uterine preg	−	Operated
86–88	Post partums 6 and 21 days	+	
89–94–95–96	Pregnancies from 2 months to full term	+ +	Case 94 a 2 months' pregnancy with incarcerated uterus abortion
102	Gonorrheal vulvitis	−	

Explanatory Signs:

+ means faintly positive.

− + means strongly positive.

− − means strongly negative, that is, no color in placenta serum dialysate or in control.

− means weakly negative, both dialysates colored, but placenta serum dialysate strongly colored.

*The negative reaction can be accounted for by the existence of lues.

‡Failure in these cases of cancer is reported by other observers also.

**The reaction begins to disappear at about the 14th day.

††I cannot account for the result in this case.

The following tests were made by the author while an assistant in the Kiel Klinik and during his activity in Prof. Abderhalden's laboratory at Halle:

It will at once be evident that the foregoing results are not perfect, nor in accord with Abderhalden's claims, but those who have followed the literature in Germany, where 95 per cent. of this work is being done, will realize that but few investigators have reported exact results. Yet I feel that my labor has not been in vain, and I am imbued with renewed hope as to the ultimate outcome of this test. Some former experiments which I have carried out at Kiel were still more unsatisfactory, but I have since acquired a host of "laboratory tricks," if I may use the expression, and every acquired knack and one's ever-increasing manipulative acumen, brings increasingly better results. The report of my predecessor in this work at the Kiel Klinik[10] was also far from perfect; but, unlike him, I am not ready to condemn the method, for I realize with Abderhalden, that one cannot be too exact in this work, that laboratory errors are always liable to occur, and that some of these I have myself committed.

To sum up, I have appended some recent precautions and will reiterate my former admonitions: (1) One must be absolutely certain that the one-half gram of placenta utilized contains in it sufficient chorionic tissue; I found in my beaker pieces that were made up almost entirely of connective tissue. Needless to add, connective tissue does not deliver peptones. To guard against this error one should utilize the spongy (chorionic) overlying layer only, and discard the rest of the placenta. (2) Where lues exists the test, to my belief, is useless. (3) Placenta, serum, test-tubes, beakers, etc., must be handled with aseptic fingers, or, better, with sterile rubber gloves, for the introduction of bacteria clouds the issue. (4) Sera should be centrifuged at least three times. (5) The placenta is best freed from its blood by means of the umbilical vessels, through which the blood is drawn, by means of a fine cannula ending in a continuous stream of cold water. (6) Placenta must be cooked at least ten times, and the drawn-off water tested with 0.2 of ninhydrin until no color appears. (7) Even certified dialyzing membranes should be tested. (8) I prefer horse serum to Seiden-peptone in determining the uniform osmotic properties of the membranes. (9) Distilled water should be used throughout. (10) The dialyzing process should consume at least sixteen hours.

In closing let me add that I look forward to a brilliant future for Abderhalden's test, not only in the determination of pregnancy, but also in numerous other fields, some of which have been already mentioned.

958 Eastern Parkway.

Case of Acute Cerebellar Ataxia in an Adult.—E. Farquhar Buzzard, reports the case of a woman, aged 38, who gives the following history: When in good health in September, 1910, on a certain day she was seized with shivering and general malaise. This continued until the following Tuesday morning, when she woke up to find herself hardly able to speak, and quite unable to use her arms or legs properly. From that time until the present there has been gradual but slow improvement, so that she is more able to talk clearly and able to use her hands for most purposes. At the same time she is still unable to stand or walk without some support. Present condition: The function of the cranial nerves is normally carried out with the exception that she displays a marked amount of ataxic dysarthria. The strength and sensibility of her arms are perfectly good, and she only displays a slight amount of cerebellar incoordination when tested severely. The lower extremities are powerful enough, but widely ataxic when she attempts to walk. There appears to be very little impairment of sense of position. There are no nystagmus, no ophthalmoscopic abnormalities, and no organic changes in the reflexes. The patient complains of no giddiness or tinnitus.—*Proceedings of the Royal Society of Medicine.*

THE ERYTHROCYTES IN ADVANCED CASES OF PULMONARY TUBERCULOSIS.

IN 1913 I. Holmgren reported before the Eleventh International Conference on Tuberculosis a symptom-complex which has since been designated by his name, and which is recognized as an unerring indication of amyloid degeneration in pulmonary tuberculosis. This symptom-complex consists of the presence of an hour-glass deformity of the nails, an enlargement of the liver, and a sclerosis of the veins. Holmgren found in 85 per cent. of his cases of pronounced amyloid disease the presence of the hour-glass configuration of the nails, and in cases with well marked hour-glass nails 88 per cent. showed other evidences of amyloid degeneration. A close connection between the changes in the nails and amyloid degeneration was postulated. Holmgren's discovery added a new sign of eminent clinical value in the diagnosis of amyloid disease.

A. Gullbring of Stockholm has studied the relationship of the red blood cells to the viscosity of the blood in advanced cases of pulmonary tuberculosis, and more recently he has studied this relationship in cases in which Holmgren's symptom-complex is present. He reports his results in the *Zeitschrift für Tuberkulose*, May, 1914. In the first place he extols Holmgren's discovery as an important means of making an early diagnosis of amyloid degeneration in cases of pulmonary tuberculosis. In his clinical studies he included among such cases of amyloid disease all those patients who in addition to a hard palpable liver presented the typical hour-glass nails. The majority of these cases had in addition albuminuria and other characteristic clinical symptoms of amyloid kidney. In studying the relationship of the red blood cells to the above symptom-complex Gullbring investigated 131 cases all of which were in the third stage of the disease, with little or no fever, no hemorrhages, no diarrhea, no apparent dyspnea, and who were up and about for the greater part of the day. The duration of the disease had been at least one year. The literature pertaining to this subject records that in certain cases of pulmonary tuberculosis of this nature the erythrocytes show a normal or increased number. In other cases, as pointed out by von Noorden, Grawitz, and Strauer, the number is reduced when amyloid disease is present. Gullbring's studies show that in advanced cases of pulmonary tuberculosis with a relatively good general condition there are obtained relatively high as well as low erythrocyte counts. As a rule the highest counts are obtained in cases in which Holmgren's symptom-complex is present. He emphasizes the fact that the presence of amyloid disease is not, as has hitherto been thought, accompanied by a diminution in the number of red blood cells, but that on the contrary these cells are increased in number in this class of cases. The discrepancies in previous studies along this line are attributed to the fact that no precise clinical sign of amyloid disease was available until the delineation of the Holmgren symptom-complex.

THE TRUE STATUS OF RADIUM IN THE TREATMENT OF CANCER.

THE value and limitations of radium in the treatment of the various types of cancer are well brought out in a recent article by H. H. Janeway (*Journal of the Am. Med. Ass'n.*, May 30, 1914), who reviews the results reported by Wickham, Dominici, Pinch, Riehl, Wertheim, and others, who have applied this treatment in about 1,700 cases. Wickham's work has been done in the Laboratoire Biologique du Radium, which was organized in 1906. Since that time 1,000 patients suffering from various types of cancer have been treated, and Wickham has summarized his opinions as to the action of radium on cancer as follows: "(1) Radium causes an undeniably destructive modification of the malignant cells. (2) Malignant tissues display a special and very selective susceptibility to the influence of radium. (3) This destructive action extends to a depth varying up to 9 cm., according to the dosage used and the sensitiveness of the neoplasm. (4) This action, even to the depth mentioned, occurs with the maintenance of relative integrity of the normal tissues traversed. (5) The action, nevertheless, is not complete enough to warrant the use of radium as a primary therapeutic agent in any form of operable cancer, with the single exception of cancer of the skin." Among other facts of special importance to be gleaned from Wickham's work are that "in a majority of epitheliomata of the skin, even in the gravest cases, radium is undoubtedly superior to any other therapeutic agent, both on account of its direct curative action and because of the simplicity of its application." Regarding other types of cancer he remarks, "Operable cancer should be operated on immediately —without delay. This is an absolutely fixed rule." In nearly all of the inoperable forms it is permissible to use radium because of the relief afforded from many of the objective and subjective symptoms. Sarcoma yields more quickly than any of the various types of cancer, while lymphadenoma and mycosis fungoides are still more susceptible. Important palliative results have been obtained in the treatment of cancer of all types and in all parts of the body. Rarely apparent cures have been obtained in some of the inoperable cases; but "in no instance, however, has there been a complete eradication of the ultimate ramifications of the disease."

As Janeway suggests, the only conclusion to be drawn from these results is that while the influence of radium on all types of cancer is a favorable one, it does not extend to the limits of the disease in any but the most superficial varieties.

At the Radium Institute of London, 467 cases of cancer were treated during 1912; and while it is too early to determine the ultimate results, there are a great many apparent cures, mostly of the epitheliomatous involvements of the skin, and the results in this institution apparently confirm Wickham's conclusions. The Vienna Radium Institute began research work in 1912, and from here reports have been made by Riehl as to the action of radium on 114 patients having cancer of the skin; by Wertheim in nine cases of inoperable cancer of the uterus; and by Ranzi, Schüller, and Sparmann, who report upon the radium treatment of six cases after operation, for the purpose of preventing recurrence, and of 47 cases of inoperable tumors of various types and in various parts of the body. The results where there was involvement of the deeper structures do not seem very encouraging as to the prospect of ultimately obtaining cures by this method of treatment, even with massive dosage, although there was often marked decrease in the subjective symptoms and sometimes considerable diminution in the size of the growth. Janeway also summarizes Caan's report upon cases treated by radium, mesothorium, and thorium-X at the Samaritan Hospital at Heidelberg. Improvement was obtained in 40 to 50 per cent. of the cases under each of these forms of treatment. This improvement consisted in the amelioration of symptoms and the retrogression of the growth but no cures are claimed, and Caan agrees with Wertheim and Wickham that in no instance where radical removal is possible should these methods of treatment supersede the knife. Another conclusion that has been forced upon many observers is that an insufficient dosage may *stimulate* tumor growth. Since the intensity of the rays diminishes inversely as the square of the distance, it is evident that the deeper portions of a growth may be stimulated into abnormally rapid proliferation even in the presence of marked retrogression of the more superficial portions.

These, then, are the facts as brought out by most painstaking investigation in several large series of cases. Incalculable harm has been done by the widespread dissemination through the lay press of gross exaggerations as to the value of radium in the treatment of cancer, and it will be devolve upon the medical profession to correct, as far as possible, the false impressions that have been given, and to emphasize strongly the fact that, for the present at least, no operable cancers, with the exception of those affecting merely the skin, should be treated by radium in preference to the knife.

FUNCTIONAL TESTS OF THE HEART.

It has long been the ideal of diagnosticians to be able to recognize in practice not only the functional capacity of an organ at a given moment, but the future outlook as well. The former task is comparatively simple, as the patient may be readily submitted to an extemporaneous strain, while the heart's action may be followed up from day to day. The ultimate outlook is not only difficult to determine *per se*, but is conditioned by affections of other organs—the kidneys, great vessels, and so on. In general, quick response to the action of cardiac stimulants is good prognostic evidence; but, as all good clinicians aver, the heart has a certain life of its own, which cannot possibly be measured or foreseen. The greatest clinicians, even when placed on their mettle by the importance of the lives concerned, have been forced to admit that hearts may be made of shoddy stuff; while good enough to pass muster under tests of all sorts, such organs suddenly cease to act even in the midst of the most vigorous pushing of analeptic remedies.

At a recent session of the Berlin Society for Internal Medicine and Pediatrics (*Münchener medizinische Wochenschrift, May* 26) Katzenstein referred to his method of increasing arterial resistance in animals—for it is in the latter that the first steps of the problem should be worked out. If a healthy dog has its abdominal aorta ligated, the blood pressure is increased until a collateral circulation is established. The vasomotor nerve system is not a whit concerned therein for the phenomena are the same after division of the spinal cord. Ligation of the abdominal aorta causes hypertrophy of the left ventricle. If this ligation is not followed by increased blood pressure, there sets in increased rapidity of the pulse, and the animal dies with dilated heart.

In man the test is simple. The two femoral arteries are compressed after their pulse beat and blood-pressure have been measured. Other measurements are then taken after the period of compression. If the heart is sufficient, no marked changes occur, and the same is true of slight insufficiency. But if the insufficiency is marked the pulse is increased and the blood pressure diminished.

THE OBJECTIVE SIGNS OF NEURASTHENIA.

Most of the symptoms of neurasthenia are purely subjective. The objective evidences are strikingly meager in comparison with the symptoms of which the patient complains. One of the common objective signs of this condition is the increased knee-reflex and the tremor of the fingers when the arms are extended with the fingers outstretched. O. Schellong (*Zeitschrift für klinische Medizin*, Vol. 80, Nos. 1 and 2) has made a study of the relative value in the diagnosis of neurasthenia of the following symptoms: the increased knee-reflex, the tâche cérébrale, the palpebral tremor, the tremor of the tongue, the tremor of the fingers, and the increased frequency of the pulse. He finds that none of these is pathognomonic of neurasthenia, for it may occur in a large percentage of healthy individuals. On the other hand, the association together of several of these signs, perhaps of four of them, enables one to conclude that there is present an increased irritability of the nervous system such as

is found in cases of neurasthenia. Even then an absolute diagnosis of this condition is not justified. A marked tremor of the tongue is present in 50 per cent. of the cases of neurasthenia, and a pronounced tremor of the fingers is also present in 50 per cent. of the cases. A prompt appearance of the tâche cérébrale is present only in 29 per cent., while an accelerated pulse of one hundred and more is present only in 24 per cent. of the cases examined. The least important symptoms from the viewpoint of the diagnosis of increased nervous irritability are the palpebral tremor and the increased knee-reflex.

Occupation Stigmata of the Teeth.

A few of these have been known of old, notably in connection with various metals. With the modern advances in dentistry and in occupation diseases much has come to light. Kraus, at a recent session of the K. K. Gesellschaft d. Aerzte, Vienna (*Berliner klinische Wochenschrift*, June 15), enumerates some of the leading occupation stigmata as follows: Confectioners are peculiarly subject to caries. The sugar dust forms oxalic acid in the mouth, and this attacks the exposed tooth to a uniform extent, as well as the root. In workers in chlorhydric acid the enamel is attacked and the dentine turns brown. Changes in the teeth are notable after the first three weeks of exposure; the teeth feel sore, and from then onward the entire crowns disappear. Unsatisfactory attempts at prevention have been made, such as a sponge held in the mouth. This absorbs the fumes of HCl, but becomes a source of irritation to the lips. Mechanical defects in the teeth are common, whenever the latter are used for tightly holding hard substances (nails), or for biting threads. The incisors naturally suffer, and it should readily be possible to state whether a tailor were right or left handed. The so-called lines above the roots of the teeth, believed formerly to have great significance, can be prevented by proper mouth hygiene, so that if all workers in copper, brass, lead, etc., were cleanly in this respect no stigmata would be in evidence.

Treatment of Malignant Tumors With Autolysates.

If carcinoma and sarcoma exert their malignant activity through the action of destructive enzymes, which doctrine has been both affirmed and denied, it is not difficult to imagine that these same enzymes may possibly cause the (sterile) autolysis of intact cancer, both during life and after death. The notion that an autolysate could possess healing power in malignancy must necessarily be a corollary of the law that enzyme activity is inhibited by accumulation of its own products. At the recent meeting of the German Surgical Society (*Muenchener medizinsche Wochenschrift, May* 19) Pflaumer sought to obtain autolysates by leaving pieces of cancer and sarcoma in the refrigerator for 3 days. Lunkenbein's technique was observed. Not an autolysate but a simple extract was obtained. The latter, however, was injected into patients with malignant disease. Irrespective of many factors—old or recent, native or foreign—these extracts caused in doses of a few centigrams a pronounced febrile action initiated with chills. If these injections were given persistently the cachectic state appeared to be postponed accordingly. Thus far no cure has resulted. In the discussion Keyser regarded this plan as an active immunisation of the body against malignancy; but to secure this result a large amount of autolysate must be injected at once. Stammler had been using autolysates intravenously for a long time, and while the combined results were indifferent, believed he had cured a case of cancer uteri.

News of the Week.

Floating Hospital In Service.—The daily trips of the floating hospital maintained by St. John's Guild, New York, were recommenced on July 6. The vessel has accommodations for 1,200 patients.

The "Sane" Fourth.—An early estimate of the fatalities resulting from the celebration of Independence Day places the number throughout the country at 15, with a total of approximately 306 persons injured, and a fire loss of $125,000. In New York City alone 76 persons were reported injured, with no deaths, and in the State outside of New York the total injured was 37. These figures show a great improvement over last year, when the deaths throughout the country numbered 30 and the injured 1,131, and a still greater improvement over six years ago when 41 deaths resulted from the celebration, 2,361 persons were injured, and the fire loss was $724,575.

Civil Service Examinations.—The New York State Civil Service Commission announces an open competitive examination to be held on July 25, 1914, for the purpose of filling vacancies in the following positions:

Assistant physician, regular, in the State Hospitals and other State and county institutions, at a salary of $1,200, increasing $100 yearly to $1,600, with maintenance. The examination is open to men and women who are licensed medical practitioners in this State and graduates of a registered medical school. Unmarried men are preferred.

Assistant physician, female, in the State Institutions for Women at Bedford Hills, Albion, and Hudson, at a salary from $1,000 to $1,200 a year, increasing $100 yearly, and maintenance. The examination is open to women who are licensed medical practitioners in this State, have graduated from a registered medical school, and since graduation have had one year's hospital experience or three years' general practice.

Assistant medical officer, Health Officer's Department, Port of New York, at a salary of $1,500. This position is in the detention and hospital service at the quarantine station, Staten Island, and requires a knowledge of cholera, plague, yellow fever, smallpox, and epidemic cerebrospinal meningitis. The examination is open only to licensed medical practitioners of the State.

County bacteriologist, Onondaga County, at a salary of $1,000 a year and expenses. Applications will be received from men and women who are graduates of recognized medical schools or colleges or of college courses in bacteriology, or who have had at least one year's training and experience in bacteriology.

Application blanks admitting to any of the above examinations will be supplied on request by the State Civil Service Commission, Albany, N. Y., before July 15.

Tokio Hospital.—A Japanese Council to arrange for the extension of St. Luke's Hospital, Tokio, was formed at a meeting held in Tokio on July 1, Count Okuma, the Japanese premier, presiding.

The hospital was established some years ago by Dr. R. B. Teusler, who was sent to Japan as a medical missionary of the Episcopal Church in this country. It is now planned to make it a thoroughly modern international hospital as a practical monument to international friendship and cooperation in medical science. Many Americans here are also interested in the project.

Traffic Accidents.—The report of the National Highways Protective Society shows that during the month of June 53 persons were killed by vehicular traffic on the streets of New York, of whom 26 were children. Automobiles and motor cycles caused the death of 29 persons, wagons of 13, and trolleys of 11.

Japanese Ambulance Surgeon.—For the first time, it is said, in New York, a Japanese has been assigned to ambulance duty. Dr. Jokichi Oguri, who was graduated from Fordham Medical College this spring, began his service at the Fordham Hospital on July 1, and has undertaken ambulance service.

Condemns Island Hospital.—The Secretary of the New York Prison Association, who was appointed by Commissioner of Charities Davis to investigate the hospital in the penitentiary on Blackwell's Island, has reported that the conditions there could not be worse and that the whole system should be reorganized. The staff consists of one physician and one hospital helper, and the hospital contains only two poorly furnished wards. The investigator recommends that at least fifty beds be provided, that one male nurse and one interne be added to the staff, and that every patient be examined on admission. Not less than 25 per cent. of the cases treated, it is said, are drug users, and with the enforcement of the Boylan law this number will probably be largely increased.

Free Health Test.—The conservation program for free examinations, chemical tests, and health reports, offered to policyholders of the Equitable Life Assurance Society throughout the United States became effective on July 1. Under this plan a policyholder whose insurance has been in force for three years or longer can obtain a free examination as to his health from the society's salaried examiners. It is believed that this will lead to the better health of the policyholders and thus to the good of the society as a whole, since with 500,000 policyholders the addition of only six months to the average life time will mean an aggregate added life time of 250,000 years.

Ptomaine Poisoning.—It is extremely difficult for the Department of Health of New York to learn how prevalent bacterial food poisoning (ptomaine poisoning) is in the city, since the only opportunity it has for studying this condition arises when a considerable number of cases in one group attracts public attention. The Department will, therefore, welcome reports of suspected cases of food poisoning from private physicians and will gladly have special investigations made if requested.

War on Rats.—The discovery of three cases of bubonic plague in New Orleans, two of which have been fatal, has resulted in a general quarantine and a widespread campaign against rats. The Health Officer of the Port of New York has declared a quarantine against New Orleans and Santiago de Cuba, and every ship coming into the harbor from any of the Southern plague ports will be thoroughly fumigated so as to destroy the fleas and infected rats, and will be required to provide rat guards to cover its mooring lines. The Public Health service has sent two of its experts to New Orleans to control the situation and has recommended that a campaign for the extermination of rats be begun at once in every port from New York to Galveston and along the Mississippi from New Orleans to St. Louis.

Dr. Charles Irving Fisher, for twenty-two years superintendent of the Presbyterian Hospital, New York, retired from office on July 1. Dr. Fisher was at one time health officer of Boston, and for eight years before coming to New York was superintendent of the Massachusetts Infirmary. He will be succeeded at the Presbyterian Hospital by Dr. Charles H. Young, who has been his assistant for some time.

Dr. Nicholas Duguet, vice-president of the French Academy of Medicine and a member of the Legion of Honor, died at his home in Paris on July 4, aged 77 years.

Gifts to Charities.—By the will of the late Miss Kate Warner of New York the Home for Incurables receives a bequest of $50,000.

The Pennsylvania Hospital, Philadelphia, has received from Mr. George W. Nevil of that city a gift of $5,000 for the endowment of a free bed in memory of Joseph and Amelia Nevil.

Obituary Notes.—Dr. AUGUST H. SCHWACKE of Charleston, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1886, died at his home on June 18, after a long illness, aged 50 years.

Dr. CHARLES JENKS SIMONS of Chicago, Ill., a graduate of the Albany Medical College in 1867, a veteran of the Civil War, and a member of the Illinois State and Chicago Medical Societies, died at his home after a long illness, on June 18, aged 71 years.

Dr. FRANK MARTIN CUNNINGHAM of Macon, Ga., a graduate of the Medical College of Virginia, Richmond, in 1899, and a member of the Medical Association of Georgia and the Bibb County Medical Society, of which he was a former president, died in the hospital of the University of Pennsylvania, Philadelphia, on June 21.

Dr. WILLIAM B. MOSELEY of Brooklyn, chief of the observation ward of the Kings County Hospital, a graduate of the University of Virginia, Department of Medicine, Charlottesville, in 1890, and a member of the New York State and Kings County Medical Societies and the Brooklyn Society of Neurology, died suddenly at the hospital, as a result of the hot weather, on June 25.

Dr. THOMAS W. EMBLEY of New York, a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1896, visiting physician to the Metropolitan Hospital, Blackwell's Island, and a member of the Homeopathic Medical Society of the County of New York, died suddenly while visiting friends in Plainfield, N. J., on June 28, aged 40 years.

Dr. GEORGE SOULE of Wickford, R. I., a graduate of the Boston University School of Medicine in 1878, died at his home, after a long illness, on June 23, aged 60 years.

Dr. GEORGE STRAWBRIDGE of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1866, founder and physician in charge of the Pennsylvania Eye and Ear Infirmary, and a member of the American Medical Association, the American Ophthalmological Society, the American Otological Society, the

Medical Society of the State of Pennsylvania, and the Philadelphia County Medical Society, died at his home in Germantown, on June 28, aged 70 years.

Obituary.

JOSEPH WILLIAM GLEITSMANN, M.D.

NEW YORK.

Dr. JOSEPH WILLIAM GLEITSMANN died in New York City on July 2, at the age of 73 years. He was born in Bamberg, Germany, in 1841, and received his medical education at Würtzburg, Munich, Berlin, and Vienna. After graduation he served in the Medical Corps of the German Army in 1866, receiving as a reward of merit the order of the Iron Cross. He also served as surgeon in the Franco-Prussian War, in 1870, and was given a medal of honor upon his retirement. Following this he came to the United States and established himself as a specialist in the department of diseases of the throat and lungs, first at Asheville, and later in New York.

Dr. Gleitsmann was a man of profound learning and a specialist of unusual ingenuity and skill, and both in this country and abroad he ranked among the foremost authorities in his department, to the literature of which he made many valuable contributions. He was a member of the American Laryngological Association, and formerly its president; of the New York Academy of Medicine; the Medical Societies of the County and State of New York; the German Medical Society, and other associations. For many years he was Professor of Laryngology and Rhinology at the New York Polyclinic Hospital and Medical School, and Laryngologist and Otologist to the German Hospital and the German Dispensary. He was also a member of the Council of the International Congress of Laryngology.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HONORS ON KING'S BIRTHDAY—ALEXANDRA DAY FESTIVAL—CAUSES OF INSANITY—SCHOOL OF TROPICAL MEDICINE—LISTER COMMEMORATION CONFERENCE—BRITISH HOSPITALS ASSOCIATION.

LONDON, June 26, 1914

THE King's birthday—Monday, the 22d inst.,—was marked as usual by the distribution of a number of honorary distinctions among men who have already achieved distinction of various kinds. There were promotions and new creations in the peerage, the baronetage, and the orders of knighthood and other orders. A few were awarded to medical men, mostly to those who have served in the army, navy, universities, and civilian offices at home, in India, or the colonies. The recipients are all well known and deserving of higher honors than they received and their number might well have been increased.

Alexandra Day, Wednesday, the 24th inst., has become a most popular festival—kept by almost everyone wearing a rose—an artificial one, of course, and the perfection of these paper flowers is a source of great admiration. They are made by 300 crippled girls who work all through the year at Groom's Crippleage, which has developed this thriving industry. Eight millions of them were sold early in the day and then the supply ran short. As the hospitals share in the profits the event has a medical interest. They were sold at almost every street corner. The sellers were ladies dressed in white relieved by wreaths of roses, etc., who volunteered for the arduous day's work—twenty thousand of them. They were mostly young and enthusiastic and groups of them were often guided and superintended by some of their older relatives. Some were up in the morning and met the earliest trains to catch the gentlemen arriving for business. At the Mansion House there were about seventy of them and the Lord Mayor and Lady Mayoress supervised and distributed them in the city localities and provided them with luncheon and tea. Every "flower girl" carried a special box into which it was requested the price of the flowers should be dropped—a penny each, but not seldom customers gave silver and not a few gold. Queen Alexandra took a drive through the streets in the afternoon and met with such a reception from enormous crowds as could not be surpassed. The enthusiasm generally at home and in the streets was unbounded—some declared it amounted to mania.

The movement has spread to the provinces and it is stated that the colonies intend to follow suit.

The Cavendish Lecture was delivered this day week before the West London Medico-Chirurgical Society by Dr. F. W. Mott, F.R.S., who took for his subject the "Causes of Insanity." After referring to the increase of the malady and the necessity of educating the public conscience on the value of research, he said there was no hope of curing until we knew the underlying causes, but the history of medical science proved that the application of physical, chemical, and biological discoveries to the study of diseases had resulted in prevention and successful treatment. His own researches into general paralysis of the insane convinced him that the cause was syphilis and the most hopeful way of combating this paralysis must be deduced from that fact. Dr. Mott then insisted that mentally defective children, particularly if more than one occurred in a family, were usually the offspring of imbeciles or of persons of low grade mentality. Though mental deficiency was not limited to any social grade, it was mostly found in the lower. Among the inefficients there would always be people of weak will, futile intelligence, and deficient moral sense; their environment was also unhygienic. These persons were prone to mate and breed, they were to an extensive degree the subjects of tuberculosis, alcoholism, and other race poisons. It was not then surprising that the next generation was likely to exhibit an increase of bodily and mental deficiency. It had been suggested that the race poisons might tend to weed out poor types, but they seemed quite as likely to produce them. Practising physicians were mostly convinced that saturation of the blood by race poisons, especially if continued in successive generations, could *per se* cause degeneracy in healthy stocks through the germ plasm.

As to mental disorders of which so far no explanation existed, Dr. Mott grouped them as toxic or degenerative. Of the first alcohol played a great part, but he doubted the statement that it was the sole or even the chief cause of admission to asylums. Every practitioner knew of people born of sound stocks that none of the usually assumed causes, such as head injury, exhaustion, overwork, shock, alcoholism, or microbic infection could render permanently insane. Delirium might be the result of

such conditions and might persist some time, but when the cause was removed the patient recovered sooner or later. Should there be neuropathic inheritance that was another thing, and any of these causes, singly or in combination, might lead to temporary or even permanent derangement. Every case of insanity must be regarded as a problem which could only be solved by full consideration of what the patient was born with and what had happened to him since.

Sir H. Burdett, referring to the question of state aid, declared that no chancellor of the exchequer would ever be strong enough to destroy the voluntary system which had saved us from the cruel abuses attached to the treatment of the people in other countries. He would rather die than live where they had state hospitals. State-aid meant that the profession dominated and humanity suffered. Dr. Mackintosh of Glasgow Western Infirmary pointed out that in the first year of the Insurance Act £123 were withdrawn because of it, but the sum was made up by new subscriptions, chiefly owing to better times in the shipyards.

The London School of Tropical Medicine has placed bronze portrait reliefs of the two chamberlains in one of the wards of the Seamen's Hospital, headquarters of the school, in commemoration of the two statesmen. The ceremony of unveiling was performed on Tuesday afternoon by the Colonial Secretary, Mr. Lewis Harcourt, and a number of distinguished supporters of the school, medical, and others were present. Mr. Joseph Chamberlain's health did not permit him to attend, but his wife and Mr. and Mrs. Austin Chamberlain were among these present. Mr. Harcourt spoke of his lifelong friendship with the Chamberlains and the pleasure of meeting on the illuminating ground of applied research. The problems of tropical disease were realized by Mr. Chamberlain when he became secretary for the colonies. He saw the need of further research and proposed the institution of such a school, which was largely due also to Sir Patrick Manson, to whose discoveries many men owed their lives, and millions of mosquitos their deaths. It was easy to suggest a school, but another thing to endow it. With characteristic energy Mr. Chamberlain did both. In May, 1899, he raised £15,000 at a banquet and by October the laboratories were built and the school opened. He afterwards raised £10,000 and this brought the beds up to 50 and equipped the museum and library. Experimental work had gone on in the laboratory and the students, about 1,800, had taken courses there and were spread over half the globe—some 700 entering the colonial medical service. The west coast of Africa, long called a death trap, would soon be thought a sanatorium. The mortality among British officials had fallen from 28 to 8 per 1,000, and the invaliding rate from 62 to 28. Mr. Austin Chamberlain, in returning thanks, said his father very early ascertained that Sir Patrick Manson was the best man to advise and cooperate in combating tropical diseases, for he had had great experience in tropical countries, and the suggestion for such an institution had been made by him. As for his own part he came in later and regarded himself as an accident, but he hoped a happy one.

The Lister biennial commemoration was held on Tuesday, the Earl of Roseberry presiding as Chancellor of the University. A number of distinguished gentlemen received honorary degrees. Sir Hector Cameron delivered the oration in which he recalled that when Lister came on the university staff, surgery was a limited, disappointing art. Anesthesia had been some time in use, but the healing of wounds was uncertain. Lister swept away the uncertainty that had dogged the steps of the surgeon up to his time and he left to the world a priceless heritage and to his profession an inspiring example. Lord Roseberry thanked the orator and said one item had been left for him to announce—the gratifying one that the managers of the Royal Infirmary had agreed to present to the university the structure of Lister's ward and lecture room in which the principles of antiseptic surgery were first expounded, in order that they might be re-erected on the university grounds as a permanent memorial to the great surgeon.

The annual conference of the British Hospitals Association this year was held at Newcastle, opening on the 19th inst. Sir George Philipson, chairman of the Royal Infirmary, welcomed the visitors, and Dr. Hume, vice-president of the Victoria Infirmary, gave an address in which he held that the effect of the Insurance Act caused increasing pressure on hospitals and changed the attitude between givers and recipients. He felt sure the voluntary system was endangered, and owing to lack of funds the hospitals, which were unsurpassed as clinical schools already finding it difficult to maintain their position. The difficulty would be increased when the working classes became generally contributors. They resented the idea of paying anything as inpatients and thought insurance provided them with free treatment everywhere.

Mr. W. G. Carnt, superintendent of the Royal Infirmary, Manchester, said the voluntary system was not a failure in that city, but coupled with contributions of a voluntary character for the maintenance of patients had been most successful.

TREATMENT OF EXOPHTHALMIC GOITER WITH PITUITARY AND THYMUS EXTRACTS—INFECTIVITY OF THE CEREBROSPINAL FLUID OF PARETICS—LANZ'S OPERATION FOR THE ASCITES OF HEPATIC CIRRHOSIS—DEGENERATION OF THE LENTICULAR NUCLEUS—TENOPLASTY IN POLIOMYELITIS—A NEW METHOD OF FORMING AN ARTIFICIAL ESOPHAGUS.

VIENNA, June 2, 1914

A SERIOUS case of exophthalmic goiter was treated successfully by Professor Pal with pituitary extract. The patient was extremely emaciated and had trembling of the hands and feet, insomnia, diarrhea, vomiting, respiratory troubles, a pulsating goiter, Graefe's symptom, etc. Within the course of two months 70 injections of increasing doses of pituitary extract were administered to the patient whose weight very soon increased. His respiration and sleep improved and the tremor subsided. Although the patient has not been cured, his condition has been considerably ameliorated. M. Englander has also reported good results in the treatment of exophthalmic goiter with thymus extract. This remedy he employs only in those cases in which neither medicinal nor operative treatment has had any effect. In the case which he presented, a girl with considerable dilatation of the heart and with a systolic murmur and a goiter, 10 weeks' treatment with thymus extract produced a remarkable result. The goiter diminished and the murmur and nervousness disappeared.

The infectivity of the cerebrospinal fluid of paretics has been confirmed by the observations of E. Mattauschek. Of four paretics there were two without any paralytic symptoms whose cerebrospinal fluid produced syphilis in rabbits, whereas inoculation with the blood of the patients did not produce syphilis. The conclusion is drawn that tabetics and paretics do not differ from syphilitic patients with respect to the infectivity of their disease. Lanz's operation for the ascites of cirrhosis of the liver was demonstrated in a case presented by H. Lorenz before the Vienna Medical Society. The method consists in opening the inguinal ring, bringing the testicle into the abdominal cavity, and sewing it in a fold of the mesentery. Through the anastomosis of the veins of the mesentery with the large veins of the pampiniform plexus there is formed an exit for the vascular engorgement resulting from cirrhosis of the liver. The method which was reported in 1911 bears a certain resemblance to Talma's operation, but the success of the latter is a variable one. The patient upon whom the Lanz operation was performed by Lorenz is now quite well and no further enlargement of his abdomen has occurred.

Progressive degeneration of the lenticular nucleus which was first described by Wilson was demonstrated by J. Zappert in a boy who presented the following symptoms: An inclination for laughter which became convulsive, a disturbance of speech, a constant twitching of the muscles of the neck and head, an intention tremor, and awkwardness in walking and in taking hold of objects. The patient is, however, able to perform all movements, there is an increased tension of his muscles, but there is no spasm. Swallowing is but little affected. The cases observed by Wilson have all been acquired. Up to the present time about fourteen cases have been described. A similar condition occurs in cases of carbon-dioxide poisoning.

The transplantation of tendons in poliomyelitis has recently been demonstrated in two cases. Both children had had their original attack in the eleventh month of life. In one of the patients both legs had been effected; power returned to the muscles with the exception of the peronei on both sides and the right quadriceps muscle. The paralytic clubfoot of the left leg was cured by sewing the tibialis anticus superiosteally to the cuboid bone. The patient can now freely move his foot. On the right leg the tensor fasciæ latæ was sewed to the patella, as the result of which operation the action of the paralyzed quadriceps muscle was replaced. The right leg can now be raised and both feet can be flexed and extended. In the second case the extensor hallucis was used as an elevator for the foot. On the right side the gastrocnemius, which was the only muscle that had retained its functional power, was used for the purpose of fixing the paralytic clubfoot as follows: the tendo Achilles was isolated and three-quarters of it were drawn through the interosseous ligament and sewed on to the cuboid bone. The patient is now able to plant his foot on the ground and to walk firmly. The operations were performed two months ago.

A new method of forming an artificial esophagus has been demonstrated by Maximilian Hirsch, who up to the present time has performed this operation successfully on dogs. More recently the operation has been performed on several patients who are now in the Vienna hospitals. The artificial esophagus is formed entirely or almost entirely from the wall of the stomach. A long rectangular flap is cut out of the anterior wall of the stomach, the defect in which is at once sewed up, and the line of suture is continued on the flap in such a manner that it is folded into the form of a tube lined with mucous membrane. This tube constitutes a new esophagus which is placed under the skin on the outside of the thorax. If the tube is long enough it can be placed in direct communication with the beginning of the esophagus. If it is not long enough an intermediate piece of skin may be used.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

GUARDING AGAINST THE PLAGUE—BACTERIOLOGICAL EXAMINATION OF THE MANILA WATER SUPPLY—PERSONALS

MANILA, P. I., May 28, 1914.

THAT the Philippines are seriously threatened with the invasion of quarantinable diseases from nearby foreign countries was well illustrated by the experiences of the past week. No less than three vessels arrived from the China coast with cases of plague aboard. One of the cases was of an unusual type and perhaps warrants being reported more or less in detail.

The S. S. *Taisang* sailed from Amoy on May 14 and arrived in Manila on May 17. The routine quarantine inspection of this vessel was made on the morning of the 17th at about 9 o'clock. A physical examination was made of each person on board and the temperature of every one taken. No cases of fever were found. The Chinese steerage passengers were then transferred to the Immigration Detention Station, from which place they were released about noon on the same day without any illness among them having been noted. At about 2 P.M. a Chinaman in the Chinese section of the city was found violently ill with a disease suspicious of plague. He was promptly transferred to the Chinese Hospital, where he died at 5 P.M., or three hours after his illness was reported. Investigation showed that he was one of the passengers who had come from Amoy that day on the S. S. *Taisang*. At the autopsy which was held on the morning of May 18, an enlarged spleen, cloudy swelling of the liver, and acute parenchymatous nephritis were found, all of which indicated that the cause of death was in all probability due to an acute infection. A careful examination for enlarged glands resulted negatively. Smears made from the spleen showed bipolar staining organisms resembling plague. After further search, a mass of enlarged glands was found under the right psoas muscle. Subsequent inoculations made into a guinea-pig resulted positively for plague. This experience shows conclusively that enlarged plague glands may be overlooked even at autopsy, and that persons in the last stages of plague may be admitted into a country in spite of the most careful quarantine inspection.

Another case occurred on the S. S. *Rubi* on May 20, while that vessel was at Cebu. The *Rubi* left Hongkong on May 12 and was inspected at Manila on May 15 in the same careful detailed manner as is mentioned above in the case of the S. S. *Taisang*, but nothing suspicious of plague was found. At Cebu a Chinese member of the crew reported himself ill, with the statement that he had been feeling badly for some days. A large bubo was found in

his right groin, which subsequently was diagnosed as plague.

Another case of plague occurred among the passengers of the S. S. *Linan,* which left Amoy May 20 and arrived in Manila on May 23. This case was detected at the quarantine inspection on account of the elevated temperature. The victim, a young Chinaman, aged 19 years, was transferred to the San Lazaro Plague Hospital, where he died a few hours after being admitted. The autopsy findings were typical for plague.

On account of the fact that the histories showed that in all probability the infection in none of these cases had occurred on board the vessels, the latter were thoroughly fumigated for rats and vermin and then released.

The Quarantine Service has issued a circular letter which provides for an inspection at Mariveles of all vessels from Amoy and a second inspection at Manila before such vessels are given pratique. There is to be no quarantine detention of vessels unless cases of plague are actually found on board. If vessels, however, are bound for other ports of entry in the Philippines where plague does not already exist, they must undergo a quarantine detention of seven days.

The bacteriological examination of the Manila water supply during the month of April gives some very interesting results. For instance, the bacterial count at the storage basin is with one or two exceptions very much lower than at a city tap. The average daily count for April at the basin was 846 colonies per c.c. and at the city tap 3,099 colonies per c.c. The bacterial count is somewhat lower in the covered basin than in the open storage basin. The average daily number of bacteria for the month in the covered basin was 740 colonies per c.c., whereas the average number in the uncovered basin was 846 colonies per c.c. It is also of interest at note that water which was pumped from the badly infected Mariquina River when treated with calcium hypochlorite so as to make a solution of 1 to 2,000,000 apparently showed no change in the bacterial count. This would indicate that calcium hypochlorite used in the strength of 1 to 2,000,000 in tropical waters which are highly charged with organic matter is insufficient and that a stronger solution will be necessary in order to produce the same results as weaker solutions do in temperate zones.

Doctor Roburg, of the Washington State Board of Health, has arrived in Manila and will pursue his studies of tropical diseases as a member of the staff, Department of Pathology, College of Medicine and Surgery, University of the Philippines.

Doctor E. A. Farrow, formerly of the Constabulary Medical Service, has resigned on account of a reduction in his grade by the recent appropriation bill and has returned to the United States. The vacancy created has been filled by the appointment of a Filipino.

Alopecia Following Severe Impetigo of the Scalp.—J. M. H. McLeod reports the case of a girl aged six on whose scalp there were a number of bald patches which were dotted over with small fibrous growths. According to the mother's statement the affection had begun two years before in the form of purulent sores on the scalp which became crusted over with a thick scab. When this separated the bald areas were left, upon which the papillomatous growths subsequently appeared.—*Proceedings of the Royal Society of Medicine.*

4. The Function of the Social Service of the Psychopathic Hospital. M. C. Jarrett.

1. Anal and Rectal Growths of Benign or Doubtful Character.—T. C. Hill notes that in his series of 3,000 rectal cases there were but forty-nine cases of benign growths. The vast majority of benign tumors of the rectum are easily recognized. The two most common varieties are the adenoid and the fibroid polyps. They may arise from any part of the rectum but are generally found in the lower two inches. Their presence is generally undetected until the pedicle has stretched sufficiently for them to protrude at the anal orifice during defecation. When found, as a prophylactic measure, they should always be removed even if causing no discomfort and of course should be submitted to examination for possible malignancy. Operative removal is simple and in most cases can be done under local anesthesia. The growth should be hooked down with the finger or instruments and the pedicle infiltrated with a weak solution of cocaine and clamped with a suitable pair of forceps as close as may be to its attachment to the rectal wall. A linen or silk ligature is next applied on the proximal side of the clamp, or if the pedicle is very broad, the latter is transfixed with the ligature and is then tied in sections. The growth is now cut away on the distal side of the clamp, the latter is removed, and in due time the ligature sloughs away.

2. Back Pain and Its Diagnosis.—H. Platt analyzes a series of thirty-two cases of lame back. These cases group themselves into the following classes: sacroiliac strain, 12; hypertrophic arthritis of lumbar spine, 7; postural back strain, 4; lumbosacral strain, 3; spondylolisthesis, 2; lumbar caries, 2; fracture of the transverse processes of the third and fourth lumbar vertebræ, 1; infectious arthritis of the lumbar spine and sacroiliac joint, 1. The outstanding complaint in all these patients was pain in the lower back, in some instances associated with pain of the sciatic type. There was no case of true sciatica or lumbago in this series, and the author did not see any such case amongst a good many other back cases in the clinic during a three-months' period, although especially on the lookout for them. Spondylolisthesis is not uncommon amongst the laboring classes; in coal heavers it is regarded almost as a normal condition. The seven examples of hypertrophic arthritis all occurred in men above the age of forty-eight who were following arduous occupations. Postural sacroiliac and lumbosacral strains present a close interrelationship; all three conditions may co-exist in the same patient, and it is not always possible to establish any definite boundary line between the several types. In four of the author's cases the chronic backache was considered to be due entirely to the obviously extremely faulty body poise present. Under the generic title of sacroiliac strain is grouped a most interesting class of cases. There are three interesting and important facts which the author emphasizes. None of the cases studied showed any gross displacement of the sacroiliac joint which was demonstrable by the *x*-ray; none of the cases presented the physical signs of relaxation of the joints; and finally no actual pathological process such as, for example, tuberculosis, was evident in any single instance.

2. **Cerebrospinal Fluid and Its Relation to Brain Tumors.**—C. H. Frazier states that tumors of any dimensions, irrespective of their size, character, or seat, may exist without signs of increased intracranial tension. Per contra, the encroachment upon the intracranial space, sufficient to give rise to the clinical picture of increased tension in cases of brain tumors (or to such physical evidences of increased pressure as may be demonstrable upon the operating table), is almost invariably the result of an excessive accumulation of cerebrospinal fluid. In many instances this will be found in the lateral ventricles, in many in the large basal cisternæ, and less frequently in the subarachnoid space over the cortex. It does not seem to make any difference where the tumor may be situated, whether in the cortex, deeper in the substance of the hemisphere, or at the base; the increase in the amount of the cerebrospinal fluid is the factor responsible for all but the focal symptoms. In subtentorial lesions this phenomenon is even more constant. The disturbances arising from an increased intracranial pressure have nothing to do with the size, situation, or character of the tumor, but rather are to be attributed to some perversion in the normal balance between the secretion and absorption of cerebrospinal fluid. The extraordinary rapidity with which the cerebrospinal fluid reaccumulates after evacuation suggests a pathogenic factor in its secretion. The relation of arterial pressure to the function of the choroid plexus has never been determined with any precision. Inasmuch as the blood pressure is not disturbed in brain tumors to any appreciable degree in any case, and not at all in most cases, to the author's mind this clearly eliminates the arterial pressure as a factor. That obstacles to correct diagnosis and localization of tumors are caused by an associated hydrocephalus is well known to neurologists. While the masking of symptoms is a matter of not common experience, the mimicry of tumor by hydrocephalic conditions is unusual. If the continued and increasing pressure of the associated hydrocephalus is effectively controlled, the prognosis of brain tumors would be less grave and the expectation of life prolonged. One has attempted in the past to meet this situation by decompression. This has been effective, however, only to a limited degree, both as to degree and duration of relief, and decompression will be more or less effective and more or less lasting in its effect if there is with the tumor an associated hydrocephalus of mild or severe grade. If the latter is the case, decompression will be less effective and less during. If the output of cerebrospinal fluid cannot be controlled, can its absorption be promoted? In the so-called puncture of the corpus callosum, as proposed by Anton, there is such a method.

4. **The Liver in Acquired Syphilis.**—By Harlow Brooks. (See MEDICAL RECORD, January 10, 1914, page 86.)

6. **Treatment of Whitlow and Felon.**—Beverley Robinson recommends the use, morning and evening, of equal parts of glycerin and a saturated solution of magnesium sulphate. Aseptic gauze should be saturated with this mixture, then covered with thin rubber tissue and a little absorbent cotton, and held in place on the finger with a narrow gauze bandage. During the day this application may be removed advantageously for a while, and the finger soaked in hot water and borax (half an ounce of borax to one pint of hot water) at least during fifteen to twenty minutes, two or three times in twenty-four hours. The borated solution is very useful in reducing local pain and redness, and probably limits the spread of the disease. Prior to its employment the author used a half saturated solution of boric acid in water, with very poor results. When the felon is well on toward recovery, after several weeks of wet dressing and soaking, oxide of zinc ointment applied at bedtime or during the day also, is notably beneficial in curing what still remains, although slight, of pain, redness, and swelling.

2. **Aerophagy.**—C. D. Aaron concludes that continued belching of gas for a considerable length of time indicates aerophagy. All eructated gas consists in the main of atmospheric air swallowed in attempting to belch. Aerophagy accompanies many neuroses and is a frequent symptom of functional and organic disease of the gastrointestinal tract. The presence of bile in the stomach contents with eructations is suggestive of aerophagy.

4. **Pyloric Obstruction in Infants.**—By William A. Downes. (See MEDICAL RECORD, June 13, 1914, page 1095.)

6. **The Treatment of Tetanus by Antitoxin.**—E. E. Irons states that it is important that the full effect of the antitoxin be obtained immediately, and this may be accomplished by giving as outlined by Park, 3,000 units intraspinally, and from 10,000 to 20,000 units intravenously at the earliest possible moment after the symptoms of tetanus appear. On the following day the intraspinal injection of 3,000 units may be repeated. The blood remains strongly antitoxic for several days. On the four or fifth day 10,000 units should be given subcutaneously to maintain the antitoxin content of the blood. It is doubtful whether the enormous doses given in some cases over periods of many days are any more effective than the more limited dosage outlined above. If only a small amount of antitoxin (3,000 units) is available it should be given intraspinally. Intraspinal and intravenous injections should be given with all the precautions usually enjoined for these methods. This use of antitoxin in no respect replaces other recognized non-specific methods of treatment in tetanus. Surgical treatment of the site of infection should be instituted at once. The patient should be placed at rest in bed in a quiet darkened room, and should receive sufficient sedatives to control convul-

sions, together with an adequate supply of fluid nourishment and attention to elimination by kidney and bowel. The necessity for large and continued doses of sedatives such as chloral or chlorbutanol should not blind the physician to the possible danger of giving an overdose. The condition of the patient should be carefully watched and a revision of the standing orders for sedatives should be made whenever the symptoms suggest the necessity for decrease or increase of dose.

2. Calculi in the Common Bile-Duct.—H. B. Robinson points out that the association of jaundice with the clinical evidence of calculi in the gall-bladder is strongly suggestive that they are also present in the common bile-duct. Accordingly when one is operating on the gall-bladder the presence of jaundice makes it imperative that the bile passages should also be investigated. This cannot be done effectually without opening the common bile-duct and proving the presence or absence of stones with the sound or scoop. Even when one is examining the gall-bladder, and there is or has been no jaundice, the bile-passages should be also thoroughly palpated as a routine measure, and in some of the cases, if not in most, a more complete investigation by sounding is fully justified. When calculi are situated in the lower end of the common bile-duct different procedures have to be adopted for their removal. Palpation in the course of the common duct, through the wall of the duodenum or to its inner side before any opening in the duct is made, may indicate that the stone is in a fixed position. This arrest may take place in the narrow part of the duct as it is piercing the duodenal wall, or in the ampulla of Veter, if it is present, or in the lower retroduodenal portion. If a lump is felt distinctly through the duodenal wall at a level consistent with the normal opening of the duct it is in one of the two former positions, and removal by a transduodenal operation is indicated. Should a lump be felt at a site above where the duct would have entered the duodenal wall, then one may employ Kocher's transduodenal method, particularly when the arrested stone is in close relation with the duodenum, or the retroduodenal method, when the duodenum is mobilized and the stone is removed from the duct behind.

4. Boots and Shoes.—E. M. Little notes that the subjects of the arthritic diathesis are peculiarly prone to suffer from painful affections of the feet. Painful flat feet, bunion, hallux flexus or rigidus, metatarsalgia, and ingrowing toenails are some of the ills that the ill-shod foot is subject to. The functions of a proper shoe should primarily be protection from cold, wet, and injury by external objects, and, secondarily, support when from any cause the foot alone is unequal to the strains to which it is liable. The shoe should closely and tightly fit the heel and what the French call the neck of the foot, as far forward as the middle of the metatarsus, while it should give plenty of room for free movement of the toes and for the normal spread of the foot when loaded with the body weight. It should above all fit easily across the bunion joint and be what is called straight on the inner edge, that is to say, the forepart of the shoe should be adducted so as to bring the great toe into the line of the first metatarsal bone. The lower the heel the better. The author refers to certain simple modifications of the normal boot to which reference may be made. In flatfoot the heel and sole may be made continuous on the inner side in order to prevent that breaking down of the waist of the boot which so often occurs and also to throw the foot onto its outer border. In the same condition the inner border may be raised a quarter or even half an inch; this has a similar effect in a more marked degree. In anterior metatarsalgia and painful corns on the forepart of the foot, whether from clawfoot or any other cause, a simple device will often entirely remove the pain and distress from which some patients suffer acutely. The author refers to the insertion of a flat plate of metal between the welt and the sole which has the effect of preventing extension of the toes, and generally limiting movement. Such plates are made of steel, or better of duralumin, which has the advantage of not corroding. If a thin layer of spongy indiarubber is put inside the boot the patient's comfort is still more promoted.

1. Murmurs in Dilated Hearts.—S. West states that dilatation of the heart is a common condition easily recognized by physical signs. Murmurs are frequently associated with dilatation and are due to it, for they come and go with it. They may be therefore very properly described as "dilatation murmurs." Murmurs are audible eddies. The conditions under which eddies form fall into two groups according as the blood is passing into or out of a dilatation of the vessels, or through a constriction in it. In order that the eddies may be audible they must be sufficiently forcible, so that they will depend upon the force of the circulation. This explains why these murmurs vary in intensity at different times, why they come and go, and sometimes why they even disappear. Of the forms in which dilatation is the prominent change the simplest is that known as mimic aneurysm. In these cases of simple dilatation murmurs are not always present; this depends partly upon the abruptness of the dilatation and partly upon the force of the circulation, but as an attack of abdominal pulsation is usually associated with palpitation, the action of the heart being rapid and forcible, the murmur is generally well marked as long as the attack lasts. A true fusiform aneurysm presents exactly the same condition except that the dilatation is permanent. Over it a systolic murmur is common. With saccular aneurysms murmurs are common though not constant. The second group of conditions which may cause the eddies necessary for the murmur is that in which the vessel is constricted, the blood having then to pass through a constriction, and having thus a dilatation, relative or absolute, both above and below, conditions the most favorable of all for the eddies required. This constriction may be produced by external pressure—by the stethoscope, for instance, or by a tumor or bony prominence pressing on the vessel. An

allied condition is that which occurs at the root of the neck, where the external jugular vein passes through the fibrous membrane, closing the thorax in the supraclavicular fossa. Constriction of a vessel is, however, more commonly produced by disease of its walls. In this case the lumen is narrowed and eddies are the necessary result. Dilatation murmurs in the heart fall into two groups, according as they occur at the base of the heart or over the body of it, and may be described as basic or ventricular respectively. Whether basic or ventricular they may be present on the right or left sides in the aortic or pulmonary areas in the one case, and over the right or left ventricles or auricles in the other. The basic murmurs are often called hemic and are referred to some altered condition of the blood, but what this altered condition is, except that there is anemia in some form, is not explained. Moreover, these murmurs vary from time to time while the blood condition remains unchanged. Anemia of any kind causing defective nutrition and therefore weakness of the cardiac muscle, will lead to dilatation, and this is easy of demonstration. Murmurs of this kind at the left base are usually called pulmonary and are assumed to be produced in the pulmonary artery. The characters of the murmurs of mitral regurgitation resulting from organic disease are well known. These murmurs are systolic in time, audible at the apex and outside it, transmitted to the axilla and to the angle of the scapula where they may be heard louder than elsewhere. The heart sounds are greatly altered. Sometimes these murmurs are not so definitely propagated. They may vary in many particulars and may at times even be absent. These variations may depend upon varying conditions in the force of the circulation or of the heart's action, but as the general rule the regurgitant murmurs are propagated as stated. The left ventricle dilatation murmurs, however, differ. They are systolic in time and as a rule softer and more blowing in character. They are definitely limited to the precordium, are heard more widely over it, and are not propagated to the axilla and back, while the heart sounds are little if at all changed.

2. **Common Errors in Diagnosis and Treatment of Cardiac Diseases.**—F. W. Price states that the most important question of all is the efficiency of the working power of the heart, and that the best method of testing this is to see how the heart responds to effort; in other words, is the patient able to undergo physical exertion without distress? Careful and detailed inquiries should be made in regard to this. In making such inquiry it is essential to remember two facts—namely, the natural standard of the heart's strength varies in each individual, and symptoms of cardiac distress on exertion may be due to some temporary or extrinsic cause, such as deficient tone from lack of physical exercise, temporary physical or mental overstrain, and anemia. With regard to the first, one healthy individual can normally perform only a moderate amount of exertion without experiencing symptoms of cardiac distress, while a second can do more, and a third can do still more. The point of inquiry should be to ascertain whether the normal standard of a particular individual has decreased, and if so, in what degree. To sum up: Provided temporary and extrinsic causes can be excluded, the fact and degree of departure from the normal standard of an individual may be taken as fairly indicative of the presence and degree of myocardial impairment or disease, and further, provided there is no other cause to account for it, and the patient has had the advantage of an adequate amount of rest, an increasing severity of the symptoms is indicative of a progressive lesion. The most common symptoms are undue breathlessness or fatigue, palpitation, precordial distress or pain, and a sense of tightness across the chest, on or after exertion.

3. **Activity and Stability of Tincture of Digitalis.**—W. L. Symes presents the following conclusions: Weak tinctures show little or no changes in a year or more. Active tinctures deteriorate much more rapidly. Of those initially within 25 per cent. of standard, all were more than 25 per cent. below standard after a year's storage. Of those initially more than 25 per cent. above standard only one-half were within 25 per cent. of standard after one year's storage, and these had lost 20-70 per cent. of their original activity. In a few samples deterioration was recognizable one month after manufacture. Few tinctures of digitalis are, initially, below standard. Tinctures, not below standard, vary 200-300 per cent. in initial activity. All such tinctures, after a variable period of constant activity, undergo deterioration, which may commence within a month of manufacture, and may amount in a year to 70 per cent. or more, of their initial activity. Concentrated alcoholic extracts of digitalis leaf compare favorably with, and behave as, the British Pharmacopœia tincture. Solutions of crystalline French digitaline are more stable than the above. Commercial "non-alcoholic" tinctures and allied preparations are not trustworthy.

Cosmetics and Anatomy.—Saalfeld, under this title, contributes an article on recent advances in dermatology. He wishes to show to what extent the prognosis for smooth recovery depends on the depth of the lesion, the more superficial being amenable in this respect. The indications have been to remove blemishes in such a manner that the skin will be left sufficiently intact and that the original lesion be not replaced by scars, stains, etc. Seborrhea and comedones can be disposed of without injuring the texture of the skin. Acne nodules may be made to disappear *en masse*. Larger lesions may heal with resulting pigmentation, which, however, is not permanent. Still larger, purulent lesions, which in the end become abscesses of the skin, tend to leave scars, because of the depth of the lesions we can only hope to abort such lesions. Aside from acne, we have to deal with noninflammatory nodules—warts, etc. These can be destroyed without compromising the skin by a combination of methods. If, however, the wart extend deeply into the derma, a raw surface must be left behind. It is often aggravated by the previous use of nitric acid, the healing being accompanied by the formation of ugly scars. Many a maiden has had her hands disfigured permanently by the repeated use of glacial acetic acid. It is better in such cases to give arsenic internally, with the external use of salicylic acid, ext. thujæ, etc. Other cosmetic blemishes are freckles and chloasma spots. Pigmented moles also belong here. To remove pigment without scar formation is the great desideratum. The cautious use of electrolysis and the galvano cautery, carbonic acid snow, etc., will decrease the amount of pigment present. Small telangiectases may be removed scarless, but in the more deeply seated angiomata scars must result from cautery, etc. These scars are, however, a great improvement over the tumors. Some of these growths yield to the *x*-ray, and are much improved, without scar formation. Premature alopecia must be considered as past all restitution, provided the individual follicles have been empty for a certain period. Some fat must be secreted, but not too much. If the scalp is hidebound the prognosis for arrest of the

alopecia is hopeless. For the rest a sharply individualized treatment may do something toward arresting the condition. The scalp should be mobilized and hyperemized. If a lanugo remains it may be developed into a thicker growth, but this happens rarely because downy hairs have no sebaceous follicles of their own.

Ocular Lesions Due to Atoxyl.—Steinebach does not accept the common conclusion that atoxyl is contraindicated under all conditions because of the innumerable cases of blindness which have followed its use. He has recently observed a case in which amblyopia of high degree followed a few small doses of the remedy. The case was summed up as follows: The woman, aged thirty-six, had been a hard drinker for years. She had never had syphilis, but had a severe itching dermatosis, the nature of which is not stated. She was somewhat cachectic. The diagnosis, as made from the principal disorder, was secondary anemia. For the latter she received a series of injections of atoxyl of small dosage. The amblyopia soon followed. The author's immediate conclusions, after patient had recovered her sight, were that the eye lesions were specific for atoxyl, and his final conclusions were to the effect that alcoholism was the predisposing factor. He believes that whatever the power of atoxyl over the eye strong predisposing factors should be present; such as cachexia (from cancer or old age), autointoxications, and certain infections of the nervous system (tabes, lues cerebri); above all, however, chronic alcoholism.

Münchener medizinische Wochenschrift.

June 9, 1914.

Origin of Arthritis.—Berg sums up his views on this subject as follows: endogenous uric acid formation depends upon some defective composition of the blood, chiefly lack of inorganic bases. Retention of uric acid due to diminished solubility of the urine is no doubt an accessory cause. So-called exogenous uric acid is really almost exclusively endogenous resting on uric acid formation during the process of secretion of the digestive fluids, when there is insufficient nutriment. It is possible that by a permanent reasonable method of living the formation of uric acid in the human organism would cease altogether. As an indicator of suitable nutriment the reaction of the urine suffices, using ordinary neutral litmus tincture. With proper diet the urine should color the latter blue, while with improper diet it reacts acid. When the urine becomes alkaline the value of the uric acid in the urine has sunk to the minimum, while the solvent property of the urine towards uric acid is greatly increased. In acid reaction of the urine we find increased formation of uric acid and a supersaturation of the urine with uric acid. The deficiency of phosphates and carbonates in an alkaline urine is seldom seen. The putrescibility of the urine seems to be less in alkaline than in acid urine.

Origin and Course of Scurvy in German Southwestern Africa.—Scherer gives an account of endemic scurvy occurring in a part of the world in which but little has been known of the disease, save that it dates back to the oldest time traceable. The affection is positively not due to an organized virus. The part played by lime salts is worth considering. Both hard and soft water are plentiful in the colony. The rainfall increases progressively from South to North, causing a great variety in the foliage. Scurvy is but little known in the North, where there is the greatest precipitation and abundant plant life. Here farms abound, and the inhabitants tend naturally to be vegetarians, living chiefly on rice, flour, and sugar. On the other hand, the drinking water in the North is very hard, ten times that in the South. The latter water, however, is correspondingly rich in alkali. The alkaline salts and alkaline earth salts possess a certain reciprocal antagonism where scorbutus is concerned. The disease is of a semimalignant type, and after eight months the mortality is from 30 to 40 per cent. The vegetarians in the North have different teeth from those in the South, and this as much as anything implies that the Southerners' diet is too poor in alkaline earths. Phosphate of lime is the best treatment for scurvy when this is of recent origin.

Deutsche medizinische Wochenschrift.

June 11, 1914.

Pancreas Achylia and Acute Pancreatitis.—Schmidt concludes that there exists a disturbance of the pancreas secretion (pancreas achylia) which is most readily and certainly recognized by the abnormal fecal findings with a test diet (creatorrhea, positive nucleus test slight steatorrhea). Further, there appears at regular intervals in pancreatic achylia intestinal dyspepsia of gastrogenic origin. The mild form of acute pancreatitis, which is chiefly a complication of gallstone disease, differs from pancreas achylia in that it begins with a crisis of pain and fever, while the feces show marked steatorrhea with abundant free fatty acids, creatorrhea being not much in evidence. The different character of the digestive disturbances is explained by the fact that in the one case achylia gastrica, equivalent to absence of HCl, the most important stimulus of trypsin secretion. In the other case of gallstone disease, the bile, which is the activator of pancreas lipase, is damaged.

Pathology and Surgery of Ulcus Duodeni.—Kümmell sums up his serial study of this subject as follows: Duodenal ulcer is not so common in Germany as in England and the United States, yet occurs in Germany in relatively large figures, often with the diagnosis of ulcus pylori. In fact, we have been ignorant of its earlier history. The family history and clinical course are chiefly so typical and characteristic that a correct diagnosis is the rule. The results of surgical therapy are to be regarded as good, the intervention is not dangerous. In any case, the ulcus duodeni seems to be a better object for treatment than the various lesions of the stomach.

Paternal Inheritance of Syphilis.—Bruck speaks of this possibility as abolished forever by modern experimental teaching. Contaminated semen we can readily understand as something different. True paternal inheritance could only imply that spermatozoids bearing spirochetes could introduce the latter into the ovum so that the forthcoming embryo would harbor them in an active or latent state. The older inoculations of spermatozoids from a recent syphilitic into apes gave negative results, but quite recent reports of Lesser and Carston seem to show that such semen has been successfully inoculated into apes and rabbits. Bruck objects that such results do not constitute proof, which would require that the spermatozoids be in a state approximating a pure culture. In any case, such a possibility is beside the mark, for the more simple explanation that the father has already rendered the mother syphilitic, and that the ovum is already infected, explains all the requirements until some one actually sees living spermatozoids actually containing the treponema. In a few cases only a newly born infant has given its mother a typical chancre of the nipple, but such a sequence, from its extreme rarity, must constitute only a superinfection.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

FISTULA IN ANO.

THE Medico-Actuarial Investigation Committee reports the mortality among persons with a history of fistula in ano calculated by the Medico-Actuarial tables based on policies issued on standard lives during the years 1885 to 1908 inclusive. The instructive cases may be divided in the following groups:

Fistula in Ano, With or Without Operation.

	Ratio of Actual to Expected Deaths
1—One attack within 2 years of application	120%
2—One attack between 2 and 5 years prior to application	136%
3—One attack between 5 and 10 years prior to application	100%

An analysis of the material from which these figures were taken showed that the death rate from tuberculosis of the lungs, cancer, and Bright's disease was several times higher than the normal in each case.

The committee was interested in determining whether fistula in ano as an impairment was of special importance among overweights or underweights. Combining those who had one attack within ten years with weights approximately 25 per cent. or more above the average weight, there were 297 cases with 26 deaths against 19.35 expected—a ratio of 134 per cent. Fistula, therefore, does not seem to be of special importance in conjunction with overweight, as the additional mortality is little, if at all, in excess of the ratio usually found among overweights.

A similar analysis of the lightweights, those approximately 15 per cent. or more underweight, showed the actual deaths to be 30 against 22.32 expected—a ratio of 134 per cent. The mortality among lightweights is not very excessive generally, so that the result is significant. Out of the 30 deaths, 13 were due to tubercular disease, a fact which seems to confirm the belief that fistula is sometimes an indication of a tubercular taint. It must be borne in mind that these underweights with a history of fistula in ano were probably selected witn special care in other respects.

If the subject is studied from a clinical and pathological point of view, it is safe to say that no definite or settled opinion can be found as to how large a proportion of cases may be due to tuberculosis. Pathological examination does prove, however, the presence of tuberculosis in at least a small proportion of anal fistulæ, and it is, therefore, important to know when the condition exists. This is particularly true in the case of lightweights as brought out by the Medico-Actuarial Investigation.

Maladies affecting the anus and rectum are numerous and of common occurrence, often causing much pain, discomfort, and mental distress. Nevertheless, the diagnosis of anal and rectal diseases has not received the attention due to it. This may be accounted for by a feeling of delicacy, especially when the patient is a woman, and an unwillingness to make the disagreeable examination more than a perfunctory one, if at all. Success is not likely to be reached as long as physicians are willing to take it for granted that nearly every rectal trouble coming to their attention is due to hemorrhoids. It is a matter of record in our large institutions that such serious disorders as fistula, ulcerations, tuberculosis, and malignant growths are not infrequently discovered among patients who come in with the story, for which their attending physicians are responsible, that they have simple hemorrhoids.

When an applicant, then, states that he has hemorrhoids, especially if he has passed middle age, there should be a searching inquiry into the symptoms and cause of this trouble. A history of pain should be investigated as to the time of its occurrence, character, and location, as it may point to fissure, ulceration, abscess, or malignant disease. The presence of a discharge will confine the diagnosis to abscess, fistula or ulceration. Inquiry should also be made as to the presence of any protrusion at the stool and loss of blood. If there is any suspicion in the case, an examination should be made. The examination, aside from the inspection of the external parts, can not be properly carried out, however, by a physician as a representative of a company, as, in order to be of any value, it must usually be partly instrumental. Instrumental examinations of any kind by a representative of a company may lead to a legal claim, sometimes justified but usually false. The only safe and feasible plan is the requirement of a certificate, furnished by the applicant, from a competent diagnostician. The applicant then assumes the entire responsibility.

Industrial Insurance.—In a paper read before the National Association for the Prevention of Tuberculosis, in Washington, D. C., on May 7-9, 1914, by Dr. J. W. Schereschewsky, Surgeon U. S. Public Health Service, it was pointed out that the citizen owes it to the state quite as much as to his own interests to see that his efficiency is not compromised by a defective state of health. If from any cause an individual suffers from defect or disease which reduces that efficiency it is manifestly unfair that the burden should be shouldered by society, if such defect or disease arose from causes which might have been personally prevented. In the opinion of the speaker industrial insurance constituted a logical means by which society might equitably distribute the costs which would result from physical inefficiency.

With regard to industrial insurance the speaker drew the following conclusions. 1. Industrial sickness insurance is an economic necessity in modern social evolution. 2. The basis upon which industrial insurance should rest is the prevention of illness and physical disabilities. 3. Frequent periodical physical examinations of workers constitute the logical means by which defects and diseases can be detected in their incipiency. 4. The scope of such examinations should be extended to include home as well as factory conditions. 5. Industrial insurance based upon preventive measures should redound greatly to the benefit of society (a) by reducing the annual loss of time through illness; (b) by establishing hygienic standards; (c) by establishing minimum hygienic standards for industries; (d) by favoring the enactment of uniform industrial legislation; (e) by increasing the efficiency of local health authorities. 6. The cost of carrying industrial insurance based on preventive principles should be less than that of the present systems.

Book Reviews.

La Stase Intestinale Chronique. Par le Docteur E. Sorrel, Ancien Interne, Lauréat des Hôpitaux de Paris et de l'Hôpital Maritime de Berck-Sur-Mer, Aide d'Anatomie des Hôpitaux. Paper, 253 pages, with 30 illustrations. Paris: G. Steinheil, Éditeur, 1914.

After a short historical note the author takes up in order the embryology of the large intestine, the description of the various types and positions of the different portions of the large intestine, the physiology of this portion of the gut and, very briefly, the etiology of stasis cases. The pathologic anatomy and theories as to the pathogeny of this subject are then discussed in great detail; and the same may be said as to the symptomatology and diagnosis of chronic intestinal stasis, dependent as it is upon so many pathologic processes which may affect the large intestine and the terminal portion of the ileum. The author then takes up the various operative procedures which have been suggested or utilized in the treatment of these cases, including the removal of bands and adhesions, fixations, and entero-anastomoses, with or without exclusion, with or without resection, all these with a wealth of detail and quotations from the work of very numerous authors, thus giving the most complete review of the subject from every angle that has ever been published. The last chapter, a résumé and the author's conclusions, brings out the main features of the subject remarkably well. A bibliography of about twenty pages, covering most, if not all, the articles of any importance that had appeared up to the close of the year 1913, rounds out this excellent thesis, and it is hard to imagine how one could have a more thorough presentation of this important subject.

The Practice of Pediatrics. By Charles Gilmore Kerley, Professor of Diseases of Children in the New York Polyclinic Medical School and Hospital; Attending Physician to the New York Nursery and Child's Hospital; Assistant Attending Physician to the Babies' Hospital; Consulting Physician to the Sevilla Home for Girls and to the New York Home for Destitute and Crippled Children; Consulting Pediatrist to the Greenwich (Conn.) Hospital, to the Tarrytown (N. Y.) Hospital, to the Englewood (N. J.) Hospital, and to the Lawrence (Bronxville) Hospital; ex-President American Pediatric Society; ex-President to the New York County Medical Society. Illustrated. Price $7.50 net. Philadelphia and London: W. B. Saunders Company, 1914.

Dr. Kerley has written a most practical textbook on pediatrics. He has extended the scope of his book on the "Treatment of the Diseases of Children" by including a larger number of diseases and by discussing their etiology symptoms, diagnosis, and prognosis, and paying as much attention as in the latter work to the subject of treatment. One of the distinguishing characteristics of the present volume is the personal note that pervades its pages. The author describes largely the results of his own experience, although he acknowledges credit to others and cites freely from the latest literature on the various subjects under discussion. Among the recent methods fully discussed is that of siphon drainage in the treatment of empyema, which method has been efficiently employed by Kenyon of New York. The subject of treatment is presented in ample detail. Definite directions are given and the doses of various drugs are indicated for particular ages of children. There are a large number of useful prescriptions. The illustrative case histories bring home in a concrete manner the subjects under discussion. One cannot subscribe entirely to all that the author teaches. Thus, he regards acute laryngitis as synonymous with spasmodic croup. This attitude is not in accord with the views of most pediatrists, particularly the English, at the present day. Acute laryngitis in children differs but little from the similar condition in adults, and is to be differentiated only with great difficulty from primary laryngeal diphtheria. Spasmodic croup, on the other hand, is characterized chiefly by its paroxysmal character and by its occurrence in children who seem to be predisposed to this condition. It is termed by most English and other European writers on this subject "laryngitis stridula." The author discusses the various dwarfing conditions in infancy in an interesting manner. Ateleiosis is misspelled "ateleosis." Considering its size, however, this volume contains remarkably few errors. It is well illustrated and contains a complete table of doses graded according to the different ages of children.

A Manual of Clinical Diagnosis by Means of Laboratory Methods. For Students, Hospital Physicians and Practitioners. By Charles E. Simon, M.D., Professor of Clinical Pathology and Experimental Medicine in the College of Physicians and Surgeons, Baltimore. Eighth edition, enlarged and thoroughly revised. Illustrated with 185 engravings and 25 plates. Price $5.00. Philadelphia and New York: Lea & Febiger, 1914.

It is pleasant to see this well-known manual appearing in a new edition, for it is among the most widely used of the works on laboratory diagnosis, and deservedly so. During the past year or two an unusually large number of new procedures have been devised and found suitable for diagnostic use, and the more important of these have been included in the present issue of Dr. Simon's book. Among them are the determination of blood sugar, Marshall's soy bean urea method; Folin's microchemical methods for determining the various nitrogenous components of blood and urine; the Abderhalden ninhydrin reaction for determining the existence of pregnancy; the technique of the gonococcus fixation test; improvements in the Wassermann technique, etc. A useful section on the application of the phenolsulphonephthalein test for renal efficiency has been introduced; but the methods for employing lactose, potassium iodide or the quantitative determination of diastase in the urine for the same purpose are not given. Other omissions of some importance are the failure to describe Benedict's methods for the estimation of urea and for the qualitative and quantitative determination of sugar in the urine, which are all very useful. A feature of especial value is the large amount of space given to the clinical aspects of the results of laboratory methods. This material is collected in a separate part of the book where the sections on the different diseases are arranged alphabetically, and under each the laboratory findings relating to the condition in question are discussed; an unusual plan, but one which has much to commend it as here carried out. All in all, the book is one of the best available and has many points of marked superiority.

Ten Sex Talks to Girls (fourteen years and older). By Irving David Steinhardt, M.D., Instructor in Clinical Surgery, Cornell University Medical School. Price $1.00 net. Philadelphia and London: J. B. Lippincott Company, 1914.

This small volume is founded on a series of lectures which the author has delivered before several organizations. They contain about the same material as can be found in the numerous other books on this subject which have appeared in the past few years. The language of the book is a curious mixture of technical terms and slang, of frankness and reserve. For instance, the author always speaks of "lower limbs," which looks decidedly out of place in a book in which the sexual organs are quite minutely described.

Some American Medical Botanists. Commemorated in Our Botanical Nomenclature. By Howard A. Kelly, M.D., LL.D. Delivered as a lecture before the Medical Historical Society of Chicago, 1910, and before the University of Nebraska, October 16, 1913. pp. 200. Price $3.00. Troy, N. Y.: The Southworth Company, 1914.

It was a happy thought of Dr. Kelly to choose for biographical sketches renowned American medical botanists whose names have been commemorated in our botanical nomenclature. Although many names have thus been handed down to posterity, the present generation has forgotten in most instances that the men who bore the names ever existed. Few are aware that that popular flower, the gardenia, was named after Dr. Samuel Garden or that the wistaria was called after Dr. Wistar of Germantown. It can be plainly seen that the writing of these sketches of our botanical medical forebears has been with the author a labor of love. The book is in every respect a fascinating one and may be recommended to the busy practitioner as a pleasant mode of evading for a while the oftime irksome duties of a toilsome profession and the bothers of a too material age. The volume is beautifully illustrated in keeping with the subject and absolutely exudes the odors of flowers and plants.

International Clinics. A Quarterly of Articles on Treatment, Medicine, Surgery, etc. Edited by Henry W. Cattell, A.M., M.D. Volume I. Twenty-fourth Series. Price $2.00. J. B. Lippincott Company, 1914.

This volume contains thirteen articles on therapeutics, medicine and surgery and a review of the progress of medicine during the year 1913. The most important papers are those of Vaughan on the Importance of Frequent Medical Examination of All Citizens and of Bierring on Thrombosis and Embolism. The review of the year's progress is very complete. This number is quite up to the usual standard for this well-known publication.

The Junior Nurse. By Charlotte A. Brown, R. N., Instructor in the Boston City Hospital; Graduate of the Boston City Hospital and Boston Lying-in Hospital Training Schools for Nurses; late Superintendent of the Hartford Hospital Training School, Hartford, Conn. Illustrated. Price $1.50. Philadelphia and New York: Lea & Febiger, 1914.

Here is a volume for nurses which actually deals with nursing and is not addressed to social workers or research students. The book contains much well selected information; most of it is of an elementary nature, but all of it is necessary for the competent nurse. The volume is well printed and attractively bound, and should prove useful not only to the beginner or pupil but also to the nurse who is interested in the practice of her profession. We have noticed a few slips which can easily be rectified in a second edition (see for example pages 71, 76, 100 and the index), but these do not materially detract from the value of the book.

A Handbook for the Postmortem Room. By Alexander G. Gibson, D.M., (Oxon.), F.R.C.P. (London), University Demonstrator in Pathology, Oxford, and Honorary Assistant Pathologist to the Radcliffe Infirmary, Oxford. Price $1.50. London: Henry Frowde Hodder & Stoughton, 1914.

The methods here dealt with are designed to cover the technique of all ordinary postmortems that are likely to be made in a general hospital and detailed methods for instances occurring with extreme rarity are omitted. The methods are based upon those of Virchow as practised in most of the schools here and abroad. Instruments, external examination of the body, examination of the organs before and after removal from the body, etc., are described.

Dental Disease in Relation to Public Health. By J. Sim Wallace, D.Sc., M.D., L.D.S. formerly Dental Surgeon and Lecturer on Dental Surgery, London Hospital. Price $3.00. London: The Dental Record, 1914.

This small volume presents a report on dental disease, in relation to public health, opens a discussion on dental hygiene in infancy and childhood, and on children and dental disease. The importance of a knowledge of the physiology of oral hygiene is insisted upon because of its neglect in textbooks. When the subject of the book receives proper attention, the author believes that dental caries and consequent and concomitant disease will cease to exist.

Pathfinders of Physiology. By J. H. Dempster, A.B., M.D., Editor of the *Detroit Medical Journal;* Lecturer in Physiology, Detroit College of Medicine. Price $1.00. Detroit: Medical Journal Company, 1914.

This volume contains brief biographies of some of the great pioneers of physiology and is both interesting and instructive.

American Red Cross Abridged Textbook on First Aid. A Manual of Instruction. By Major Charles Lynch, Medical Corps, United States Army, and First Lieut. M. J. Shields, Medical Reserve Corps, United States Army. Prepared and endorsed by the American Red Cross. With illustrations. Price 30 cents. Philadelphia: P. Blakiston's Son & Co., 1913.

We have before us four small volumes which form a series. These are especially indicated as being Railroad edition, Police and Firemen's edition, Miners' edition, and Women's edition. As knowledge of certain facts is necessary to all students of first aid to the injured, a great part of each of these volumes is common to all. The last chapter or two contains the special information which is required by the individual of the class for whom each volume is written. Each book contains instructions on: What first aid is; general directions, shock, bandages, bruises, strains, sprains, dislocations, fractures, wounds, bleeding, burns and scalds, sunstroke and heat exhaustion, frost bite and freezing, suffocation and artificial respiration, drowning, electric shock, gas poisoning, hanging, unconsciousness or insensibility, and poisoning. The Miners' edition gives extra chapters on how to carry the injured, miners' first aid, safety and care of the injured, and organization of first aid instruction. The Railroad edition has extra chapters on how to carry the injured, railroad and shop first aid, including safety and care of the injured. The Police and Firemen's edition contains chapters on how to carry the injured and special first aid for police and firemen. The Woman's edition contains special chapters on common emergencies, and carrying and home preparations for sick and injured. The books are well printed, and the instruction given is serviceable and practicable. The price of each volume is remarkably low.

Medical Gynecology. By Samuel Wyllis Bandler, M.D., Fellow of the American Association of Obstetricians and Gynecologists; Adjunct Professor of Diseases of Women, New York Postgraduate Medical School and Hospital; Associate Attending Gynecologist to the Beth Israel Hospital, New York City. Third Edition. Thoroughly Revised, with Original Illustrations. Price, $5.00 net. Philadelphia and London: W. B. Saunders Company, 1914.

The appearance of the third edition of this well-known work comes at a most opportune time, coinciding with the renewed attention that is being given to the subject of internal secretions in gynecology. The author has emphasized the importance of this subject in the first two editions but in the present volume he devotes considerably more space to this topic, which exemplifies more than anything else the efficiency of medical treatment in gynecology. A separate section of 53 pages discuses the general aspects of the internal secretions, including those of the pineal gland, the thymus, the parathyroids, the thyroid, and the hypothysis, and there are also discussed the function of the ovaries and their relation to normal and pathological states, hypergenitalism, hypogenitalism, and skin affections with reference to the internal secretions. The internal secretions are again alluded to in the chapter on the associated nervous conditions in gynecology. The rôle of the internal secretions is most forcibly presented in the discussion in what the author describes as constitutional dysmenorrhea. Thus, he notes that the constitutional phenomena that are associated with the premenstrual changes or so-called nervousness, are in many cases evidences of hyperthyroidism. This is also manifest in many cases preceding the menopause. On the other hand, symptoms of depression at these periods may be evidence of hypothyroidism. The administration of the thyroid gland aids in the diagnosis. In other respects this volume maintains the high standard which it has already reached in the discussion of all those numerous resources which are at the disposal of the general practitioner in the treatment of gynecological disorders. The book is fully illustrated. The directions for treatment are given in minute detail with the aid of many prescriptions. As a reliable guide for the student and practitioner this work may be recommended without reserve.

Blood Pressure in General Practice. By Percival Nicholson, M.D. With ten illustrations. Second Edition. Price $1.50. Philadelphia and London: J. B. Lippincott Company, 1914.

The significance and importance of blood pressure have been recognized only within comparatively recent times, and consequently the medical practitioner is often at a loss as to how to determine it and to apply it clinically when determined. It was therefore with the object of placing in the hands of the general practitioner a handy book in which was set down in concise language modern views as to blood pressure and up to date methods of determining the same that Dr. Nicholson issued this volume. It may be said that the author has succeeded well in fulfilling his self-imposed task and his book may be recommended as a useful condensed review of the subject of of blood pressure from the present aspect.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixty-fifth Annual Meeting, Held in Atlantic City, June 22, 23, 24, 25, and 26, 1914.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 43.*)

SECTION ON SURGERY.

Thursday, June 25—Third Day.

Anoci-Association in Relation to Operations on the Gall-Bladder and the Stomach.—Dr. GEORGE W. CRILE of Cleveland said that there was a certain degree of exhaustion due to infection, to indigestion, to starvation, and other possible causes in patients requiring operations on the gall-bladder or stomach. He presented evidence of morphological changes in the brain, liver, and adrenal gland in patients with operative stomach and bladder conditions identical with changes due to emotional states such as fear and anger. Toxins and fatigue cause similar changes. There were acid changes in the blood or increased H-ions along with the above changes. The margin of safety for each patient depended upon the existing exhaustive changes in the above organs and acidosis. To raise the margin of safety he advocated increasing the store of energy and diminishing possible exhaustive changes. He eliminated worry and excitement, increasing the patient's confidence as far as possible. He administered morphine sulphate, 1/6 gr., and scopolamine-hydrobromide, 1/150 gr., before operation, novocain, 1-400 sol. subcutaneously, or quinine and urea hydrochloride, 1-600, intramuscularly and used a general anesthetic when necessary. Speaking of postoperative pneumonia, Dr. Crile said he had prevented the occurrence of a single case during the past year in his hospital service by preventing postoperative pain which, he held, brought about pulmonary stasis, which may or may not develop into pneumonia.

Dr. W. D. HAGGARD of Nashville favored the excision of the thickened indurated gall-bladder and praised the combination of the surgical laboratory and surgical clinic.

Dr. ERNEST LAPLACE of Philadelphia considered all kinds of shock of the same fundamental nature, and, therefore, minimized by an amelioration of any of the respective causes. He favored the removal of the gall-bladder with seriously impaired function and exhibited a liver-retracter which facilitated its removal.

Dr. ROBERT MORRIS of New York expressed his belief that he had helped to provoke anoci-association by his 1½-inch incision.

Dr. A. J. OCHSNER of Chicago said it was fundamental to widen the margin of safety. He felt that Crile's innocuous method accomplished this.

Dr. HOWELL of Columbus, expressing admiration for Crile's method, administered veronal in 10-gr. doses, followed by morphine sulphate in divided doses to his preoperative patients. He found that quinine and ureahydrochloride injected into the skin caused a slough, interfering with union.

Dr. CRILE, in conclusion, advised the administration of morphine in selected cases and warned against the injection of quinine and urea hydrochloride into the skin.

The Problem of Intestinal Obstruction: Effort to Explain Variable Clinical and Experimental Results.—Dr. FRED T. MURPHY of St. Louis quoted a number of observers who generally agreed that death in obstruction was due to toxemia. This toxemia depended upon its production and toxicity for its severity. He reconciled the contentions of Hartwell and of the Hopkins Laboratory in part. They differed in the origin of the toxin. Murphy concluded that toxin caused death in obstruction, that the toxin was bacterial in origin, and varied with the duration of the obstruction. He said the toxin might enter the system through the thoracic duct and that obstructive death was not marked by peritonitis or general blood invasion. He concluded further that interference with circulation of obstructed loop was necessary for absorption, and advised resection rather than drainage for such a portion of intestine. Dogs with excluded jejunal loops die without peritonitis. He pointed out that high loops produced the greatest accumulations of secretion with distention, while the low loops produced the least secretion and were tolerated longer. He maintained that a sterilized loop produced no symptoms until after infection. The same applied to obstructive gall-bladders. He looked upon the toxin as a ptomaine.

Dr. J. W. DRAPER of New York opened the discussion. He presented two very potent reasons for believing obstructive death due to a toxemia is of a biochemical nature. In the first place, obstruction at the cephalad end of the intestinal tract which was comparatively sterile, was particularly fatal, whereas obstruction at the caudad end which was rich in infectious material was well tolerated. He further showed that if you feed duodenally obstructed dogs cells from the jejunum and ileum of healthy dogs it will prolong the life of the obstructed dogs once again as long as the control dog. He pointed out that this prolongation of life resembled somewhat that produced by feeding doubly nephrectomized dogs kidney tissue. These facts were emphasized by a series of carefully arranged lantern slides.

Dr. J. A. HARTWELL of New York denied the sterility of the upper intestine, affirming that there were considerable organisms always present to infect obstructed loops. He drew attention to the importance of water supply to dogs with high intestinal obstruction where the water loss is considerable and to the comparative unimportance of water to dogs with low obstruction. He held, in addition to brain, liver, and renal glands, the kidneys and the body tissues in general could be shown to suffer from the effects of a toxemia.

Dr. MURPHY, in conclusion, said that he considered feeding experiments unreliable and denied the relative sterility of the upper intestinal tract.

Internal Hernia Due to an Aberrant Middle Colic Artery.—Dr. ALEXANDER PRIMROSE of Toronto reported a case of internal hernia due to an aberrant middle colic artery which arose from the right common iliac and formed the mouth of a pouch containing the entire small intestine. He pointed out other locations where similar internal hernias might occur, including the duodenal jejunum junction, the sigmoid, and the ileocolic junction. He mentioned particularly the foramen of Winslow, and by it emphasized the gravity of dealing radically with such hernia. The imminent relation of important blood vessels made it impossible to relieve the hernia without seriously interfering with the nutrition of some portion of the intestine.

Dr. C. A. POWERS of Denver commended Dr. Primrose on his conservative judgment of internal hernias.

Dr. W. A. COLEY of New York reported a similar case of inter-sigmoid hernia where he was compelled to operate to relieve obstruction and overcome the effects of rupture.

Dr. E. W. ANDREWS of Chicago considered hernias of such character inoperable. He recognized the necessity of relieving strangulation where in an attempt to save life intestinal anastomosis might be necessary. He favored classifying internal hernias under intestinal obstruction.

The Rodman Operation for Cancer of the Breast.—Dr. DONALD GUTHRIE of Sayre, Pa., described the Rodman operation for cancer of the breast. He described the technique carefully considering it to be of considerable value to dissect away from the axilla. This revealed the extent of axillary involvement and cutting across the lymphatics prevented further extension during the traumatism of the operation. He said that skin grafts were seldom necessary and that limited arm function due to cicatrix was very unusual.

Cancer Vaccine and Anticancer Globulins as an Aid in the Surgical Treatment of Malignancy.—Dr. J. W. VAUGHAN of Detroit called the cancer cell a protein cell with toxic and nontoxic groupings, the former when injected into the body intoxicated, the latter sensitized to cancer-globulin. Intraperitoneal injection was associated with the greatest reaction because of the exposure of the greatest number of body cells to foreign protein. He presented the problem of using up the antiferment produced at each injection of ferment that the ferment injected might be free to attack the cancer tissue. Dr. Vaughan concluded his talk by recommending the use of his cancer vaccine in connection with operation for cancer.

Dr. PARKER SYMS of New York, discussing, said he believed that every case of chronic cystic mastitis should be regarded as potential cancer and treated by radical operation in all instances.

Dr. W. L. RODMAN of Philadelphia explained that his operation had been originated so as to embrace the good points from operations of Halstead, Meyer,

Harold Stiles, and others. Of fifty cases operated upon for cancer of the breast, 78 per cent. were found living after three years.

Dr. Joseph Bloodgood of Baltimore declared that results as he saw them of the younger men were, in general, equal to the results of the older men of greater experience. He emphasized the wide dissection of fat and fascia overlying cancer. He declared that the wall dissection was more important than axillary dissection, but that most important of all was the ability to diagnose any breast lesion when first met with.

Dr. W. B. Coley of New York outlined briefly the different means of producing or of attempting to produce immunity to cancer.

Dr. M. M. Lucid of Cortland, N. Y., emphasized early diagnosis and sharp knife dissection.

Dr. Weider of Philadelphia pointed to the importance of frozen section study in the operating room.

Dr. Jacobson of Toledo declared that the Rodman operation was alone free from the complication of lymphedema of the arm.

Dr. Guthrie in conclusion said that in postoperative cases he used the *x*-ray for one year following operation.

Dr. Vaughan in conclusion added that vaccine was given according to increased mononuclears. He advised operation after vaccination when the ferment was free in the blood stream.

The Standardization of the Surgeon.—Dr. J. T. Finney of Baltimore enumerated the difficulties of establishing the standard of one desiring to practise surgery. He recommended leaving physical and temperamental requirements with the teachers of the medical schools. Speaking of professional requirements, Dr. Finney held that the abuses of fee-splitting, self-advertisement, and extortionate fees should be left with the surgical society to correct. He said that the technique of private life should be spotless. He held that he was guilty of misdemeanor who while unfit for surgery practised surgery, for he was pretending to possess that which he did not have. Charges should be based upon professional training, special skill, and the financial status of the patient.

The Standardization of the Surgical Clinics.—Dr. F. D. Gilbreth of New York said that surgery presented an ideal example for motion study especially in respect to the surgeon as a worker and his equipment. Speaking of his instruments he said they were very poor and too many. Surgeons' methods were numerous in spite of the fact that there could be but one perfect method. He illustrated the fact that uniformity of method saved time and effort. He recommended the organization of one hospital where the best surgeons might operate in the best way with standardized instruments.

The Surgical Service in Hospitals.—Dr. H. O. Collins of Minneapolis said that the choice of materials for hospital use should be left to a conference between the surgeons and the administration. Choice of the nurse for any particular case should be left with the administration. The preparation of patients for operation in each hospital should be agreed upon and left with the internes to arrange for. The operating room should of course be ideally equipped and in it there should be tolerated one uniform method of performing each operation. Uniformity of method was facilitated by having an organization comprising a surgical chief who would be responsible for all operations performed within his hospital, associates who should be qualified to operate, and assistants whose function it was to arrange the patients for operations. None of the associates should operate without the knowledge of the chief. Both the associates and the assistants should be chosen by the superintendent upon the nomination of the surgical chief.

Dr. R. E. Dickenson of Brooklyn reviewed Gilbreth's talk as he saw it.

Dr. MacGee of Burlington expressed himself opposed to the limitation of the medical student who he declared was licensed to practise both medicine and surgery.

Dr. J. A. Hornesby of Chicago pleaded for more economical hospital management and recommended cooperation between the surgeons and administrators to accomplish that end.

Dr. H. T. Sutton of Ohio suggested that the conscience of the operative surgeon be considered a requisite for his license to practise surgery.

Dr. Finney in conclusion explained it was his hope to suppress unethical and immoral practices.

Hodgkin's Disease.—Dr. J. L. Yates of Milwaukee ascribed high mortality of Hodgkin's disease to its unknown etiology. It was curable in early stages. To effect its cure it was necessary to remove the focus of infection and prevent its extension to other foci. Vaccine therapy produced improvement but not beyond that of other methods of treatment.

Dr. G. W. Crile of Cleveland held the value of vaccine study lay in its relation to cancer and the ductless glands.

Dr. J. T. Ochsner of Chicago expressed the view that Hodgkin's disease was an infection. He thought the elimination of the harbor of entry and of infected food would prevent the disease.

Dr. E. W. Andrews of Chicago related his experience in the study of the etiology of Hodgkin's disease.

Dr. Yates concluded that there was a characteristic clinical and microscopical picture for Hodgkin's disease, that no case could be considered cured that gave any microscopical evidence of the disease within six years following the treatment, and that judged according to these standards he had two cases absolutely well.

Penetrating Wounds of the Abdomen.—Dr. Ralph Winslow of Baltimore discussed his personal experience with gunshot wounds and stab-wounds of the abdomen. While prompt laparotomy was the wisest procedure for them in civil practice it was apparently prudent to trust to nature in military practice. Treatment included arrest of hemorrhage, the establishment of efficient drainage. Fowler's position, and rectal instillation.

Dr. E. LaPlace of Philadelphia emphatically pleaded for immediate operation when the knowledge of a bullet within the abdomen was obtained.

Dr. C. Wilson of Birmingham, Ala., reported for his first twenty-five cases ten deaths, and for his second twenty-four cases sixty-five per cent. mortality.

Dr. Jacob Frank of Chicago said penetrating abdominal wounds in military practice were sealed up to keep out ectogenic infection, although septic peritonitis developed twelve hours later. He recommended insertion of a drain to keep the wounds open.

Dr. Ford of U. S. A. added it was military practice not to touch gunshot wounds of the abdomen. Of those operated upon all died, while of those not operated upon some had recovered.

Dr. F. N. McRae of Atlanta recommended prompt operative treatment for penetrating wounds in civil practice.

Dr. W. L. Rodman of Philadelphia quoted authority for fifteen per cent. mortality from operation for penetrating abdominal wounds within the first twelve hours, 44.6 per cent. for second twelve hours, 67 per cent. for third twelve hours and 70 per cent. for fourth twelve hours. He advised flushing out of the abdomen in late cases of penetrating abdominal wounds where there had been extensive soiling of the peritoneum.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, March 16, 1914.

The President, Dr. Thomas S. Southworth, in the Chair.

Presentation of a New Cystoscope and Gastroscope.—Dr. Julius London demonstrated a new cystoscope and gastroscope which he had devised.

The Differential Value of Cyclic Indicanuria in Gastrointestinal Diseases.—Dr. Gustave Baar of Portland, Ore., and Carlsbad, Austria, read a paper on this subject, in which the practical results of his studies, extending over several years, were summed up as follows: (1) Instead of guessing at the diagnosis in cases coming under observation in which there were indefinite gastrointestinal symptoms, we should test the urine regularly for indican, and, after having made twenty or thirty such tests we should be able to make a diagnosis. Only repeated examinations for indican would throw any light on those obscure lesions of the gastrointestinal tract which for years might not have shown any definite symptoms. (2) We should practise high colonic lavage, for a few weeks, in order to be assured that the indican did not form in the lower colon. (3) We should watch the gastric juice for achlorhydria, to exclude this possible cause of indicanuria. If we made these tests we would find that we

could divide the indicanuria cases into three types: (1) Transitory indicanuria, due to some temporary anatomical lesion or insufficiency of gastrointestinal secretions (psychic). (2) Constant indicanuria, due to permanent or progressive anatomical lesions of the gastrointestinal tract or to permanent insufficiency of the gastrointestinal secretions (earmarks of hypoplastic constitutional anomaly). In this latter class of cases, about 1½ per cent. of all, we could remove indicanuria, and many of the clinical symptoms, by high colonic lavage. (3) Recurrent indicanuria, due to some recurrent anatomical lesion of the gastrointestinal tract. High colonic lavage would remove this type of indicanuria only when the lesion was located in the colon, having no effect whatever when it was higher up. In these cases cyclic indicanuria was quite often the only positive evidence of gastrointestinal lesions which called for surgical interference (chronic appendicitis, cholecystitis; ulcer of stomach or duodenum). The acceptance into our diagnostic armamentarium of the symptom of cyclic indicanuria would, the speaker trusted, help to reduce the number of so-called intestinal neurasthenics and hypochondriacs, reduce the mortality of gallstone operations, because of an earlier diagnosis of atypical cases, prevent gastric ulcers from remaining unrecognized until perforation occurred or cancer developed on their bases, and cure a large number of "nervous" hyperacidity cases by removing the anatomical substratum of such.

Dr. William H. Porter said that frequently repeated examinations of the urine for a considerable time—for days and weeks in steady succession—was the only way in which we could arrive at any satisfactory conclusions regarding indicanuria and its relation to metabolic disturbances. In the case of one patient he had had the opportunity of examining a specimen of urine every twelve hours successively for eighteen months, and this afforded a wonderful revelation as to the true significance of indicanuria. There were many phases of the subject, as he had found by this series, and by examining some three or four thousand other specimens during the past two years. One of these was the fact that that all forms of indicanuria have as their cause an arrest of the normal flow of the digestive secretory ferments, however brought about; and also that just as soon as we could re-establish the normal flow of these ferments the indicanuria would disappear. Hence, in all these cases, this was the main thing to accomplish. In the case referred to, which was that of a gentleman with enlarged prostate, the indicanuria did not yield to any kind of treatment until the pain from which he suffered had been relieved. Relief was very promptly afforded by minute doses of powdered opium combined with potassium bromide and extract of valerian, and with the relief of the bladder pain and spasm there came an augmentation of the digestive ferments and a rapid disappearance of the indicanuria. Furthermore, this was more or less permanent for weeks thereafter. Dr. Porter had observed many instances in which troublesome nervous disturbances associated with indicanuria had continued as long as the digestive secretory ferments were not adequately produced, and in which just as soon as they were, all abnormal symptoms were removable.

Dr. Louis F. Bishop said that the idea, still retained by many, that indicanuria is often dependent upon constipation, should have been exploded long ago. In his own work, especially regarding the problem of arteriosclerosis, he had become impressed by the importance of indicanuria of metabolic origin. Thus, indicanuria was a constant accompaniment of advanced arteriosclerosis with high blood pressure, discomfort in the region of the heart, threatened apoplexy, etc. Everyone recognized that the animal protein elements in the food are the ones most concerned, and recent work at the Rockefeller Institute, pointing to the comparative simplicity of the digestive processes pertaining to protein foods in the intestinal tract and to the fact that the amino acids are stored in the tissues, leaving the more elaborate changes for a later period, emphasized the importance of metabolism. This fact, that protein foods are quickly broken up and pass into the tissues, from which they are taken up and dealt with by the chemical processes of the body, indicated that the processes within the intestine are of much less importance than was formerly supposed. Arteriosclerosis represented the result of that disturbance of metabolism which was of most importance to the human race. It consisted of the direct damage to the cells of the body by materials, of food and bacterial origin, to which the cells are sensitive. Somehow, during this process, indican appeared in the urine, and this indicanuria was of a most intractable type and, from his own point of view, had overbalanced in importance the intestinal indicanuria to which he had formerly paid as much attention as anyone else. Dr. Baar's point that a lesion in the intestinal mucosa would permit the passage of indican into the circulation was interesting to him because, if this were the case, it was possible that crude proteins, leading to sensitization of cells, might also gain entrance to the circulation.

Dr. Edward Waitzfelder stated that indicanuria was an evidence, not of intestinal fermentation, but of intestinal putrefaction. There was always a small amount of indican in normal urine, and it was only when it was in excess that it was indicative of a pathological condition. After some remarks on certain abnormal digestive conditions and processes and their results, he went on to say that the value of the presence of indicanuria was not that it indicated intestinal putrefaction, but that it showed that there was present some abnormal condition, anatomical or physiological, which interfered with the functions of the abdominal viscera in maintaining a proper balance between the benign and the malign intestinal bacteria. The rate of flow and quality of the blood-stream within the abdominal cavity was not the least important element in this matter. Congestion meant stasis, and stasis meant a change in the alkalinity and osmotic properties of the blood, with a resulting new culture medium within the digestive tract. Any focus of irritation within (and sometimes without) the abdominal cavity might be sufficient to give rise to a "reflex" manifesting itself in intraabdominal congestion. It was in this way that indicanuria was produced as a symptom of chronic appendicitis, lesions in or about the gallbladder, gastric or duodenal ulcer, pathological conditions in the female pelvis, etc. These were the so-called surgical causes of indicanuria, and the cases constituted but a small proportion of those in which this was present. The medical cases of persistent indicanuria were far more frequent, and usually followed an error in diet or were of psychic or nervous origin. It was well known that psychic disturbances caused a change in the splanchnic blood supply, and it was along this line that an explanation might be sought for the functional neuroses. Toxemia resulting from the action of abnormal microorganisms in the gastrointestinal tract produced an irritation of the higher nervous centers in the medulla and upper spinal cord, at the origin of the sympathetic; manifesting itself by an alteration in the rate of flow in the abdominal blood-vessels. In this way a vicious circle was established. The irritation of these higher nervous centers, if continued sufficiently long, resulted in anatomical change; cellular degeneration took place, a morbid anatomical condition supplanted a morbid physiological one, and, as in all other pathological conditions where nerve cells were destroyed, complete restoration of function was impossible. The examination of urine for indican should be as much a routine as that for albumin or sugar, for indicanuria was frequently the first symptom of a condition which, if allowed to go on unchecked, would result in the most serious consequences. It was, however, but a symptom, and treatment should be directed against the cause producing it.

Dr. Baar said that Dr. Bishop's contention regarding indicanuria, however plausible it might appear, was certainly not yet proved. In the paper he had propounded no theories, but had confined himself strictly to facts in regard to cyclic indicanuria. In gastrointestinal cases where a diagnosis could not be made, 24-hour specimens of urine should be examined every second day for six weeks. Usually between 30 and 40 tests were required in order to arrive at satisfactory conclusions, and where symptoms of abdominal or pelvic disturbance persisted, the patient ought to be cut open. Cyclic indicanuria associated with vague symptoms of this character constituted a surgical case.

Report of Fifty-four Cases of Lobar Pneumonia Treated by a Special Method.—Dr. Edward E. Cornwall, after having summarized the clinical features of these 54 consecutive hospital cases, stated that there occurred four deaths, giving a mortality of 7.4 per cent.; while two of the patients were moribund when admitted. A fifth patient died two weeks after apparent recovery from his pneumonia, but as his death was due to another disease, it was not included among

the pneumonia fatalities. The special method employed in this series of cases, he said, exploited no new drug, nor any old one in extraordinary dose; nor did it include vaccines, though the door was left open for them. It was essentially a physiological method, aiming solely to put and keep the patient in the condition he would be able most easily to cure himself, and to ward away from him everything tending to interfere with the natural process of recovery. A point in the hygiene considered of importance was to temper the cold fresh air to the afebrile patient. During the febrile period of a well-marked lobar pneumonia the fresh air should be cold, but in the aged and in cases with little or no fever, and always after defervescence, the patient should be kept warm and protected from drafts. A particular and essential feature of this treatment was the regulation of the diet along the following lines: The amounts of protein and fuel given were less than in the minimum health rations, the diet as a whole was nonputrefactive, and it included a sufficient quantity of the food salts needed by the body, especially calcium salts, of which there was reason to suspect that a deficiency regularly existed in pneumonia. The purpose of this diet was to supply nourishment sufficient to carry the patient through the short period of the disease with a minimum of trouble from the alimentary tract, that region of special danger in pneumonia, whence might come general poisoning, vasomotor paralysis, nervous disturbances of the heart through the reflexes, and mechanical disturbances from distention. The speaker then described in detail the diet he was accustomed to order. Prescription 1, to be taken during the febrile period and for at least three days after defervescence, was as follows: 8 A.M. Give 7½ ounces of a two-to-one mixture of milk and barley water, to which has been added 5 grains of sodium chloride. 8:30 A.M. 12 grains of calcium chloride dissolved in 5 ounces of water. 10 A.M. 7½ ounces of the milk and barley mixture. 11 A.M. 7½ ounces of orangeade, made with the strained juice of one orange and 1 ounce of milk sugar. 12 M. 7½ ounces milk and barley mixture. 12:30 P.M. 12 grains of calcium chloride in water, as before. 2 P.M. 7½ ounces milk and barley mixture. 3 P.M. 7½ ounces of orangeade, as before. 4 P.M. 7½ ounces milk and barley mixture. 4:30 P.M. 12 grains of calcium chloride in water. 6 P.M. 7½ ounces milk and barley mixture. 8 P.M. 7½ ounces milk and barley mixture. 8:30 P.M. 12 grains of calcium chloride in water. 11:45 P.M. 7½ ounces of orangeade. 11:55 P.M. 12 grains of calcium chloride in water. Administer everything through a tube, without raising the patient's head. This prescription, which supplied about 38 grams of protein, and fuel to the value of 1,200 calories, 35 grains of sodium chloride and 60 grains of calcium chloride, in addition to the salts in the articles of food given, and 95 ounces of water, served as a standard diet, and a maximum diet, except in regard to water, which might be given freely in addition, if desired. Certain modifications of this prescription, to be used under special circumstances, were also given. Later a somewhat more liberal diet was allowed, as in prescription 2, to be taken on the fourth day after defervescence in uncomplicated cases, and prescription 3, on the seventh day after defervescence, or as soon as convalescence was assured. Another essential and characteristic feature of this treatment was extreme caution and reserve in the use of cathartics, as his clinical experience had convinced him that patients would generally do better if their bowels were not much or often disturbed by artificial evacuents; provided that they were fed according to the plan described. Under the nonputrefactive, limited diet recommended the bowel contents were generally harmless. There could be no question, however, that if in the beginning of the attack the bowels had not moved within a reasonable time, a gentle laxative should be given. A vegetable cathartic, such as castor oil, was preferred, and the popular calomel and Epsom salt were looked upon with disfavor, either then or later, as adding materially to the gravity of the prognosis. The artificial induction of a bowel movement, by any means, near the time of crisis, or when the heart was undergoing strain, seemed to be contraindicated. In this treatment, after an initial gentle purge, simple enemata were given every second day, if the patient was in good condition, until the expected time of the crisis (usually about the fifth day), and after that time, or at any time if there were signs of heart strain, the bowels were not disturbed. The treatment of symptoms, according to this method, was distinguished by conservatism, and a few points in this connection were referred to by Dr. Cornwall. For severe pain in the early period morphine or codeine was given in moderate doses, but later on, especially near the time of crisis or at any time when there was much respiratory embarrassment, opiates were strictly avoided. Hot poultices were sometimes applied for severe thoracic pain. For restlessness, sodium bromide was the preferred drug. If delirium incited the patient to get out of bed, physical restraint was employed. In case of gastric irritability, diarrhea, or tympanites, reduction of the diet was the only treatment given. Stimulation of the heart was required more often than not, except in children, and in the aged, alcoholics, and patients with preexisting myocardial disease it was employed from the beginning. It was considered more desirable to begin this a little before it was actually needed than to wait until the heart had suffered from lack of it. Strychnine sulphate was regarded as the most useful drug, and if more stimulation were needed, tincture of strophanthus was given in addition. In exceptional instances caffeine citrate was also employed, and where there was an obstinately dilated ventricle, digitalin was administered hypodermically. In cases with extremely low blood-pressure adrenalin was given, hypodermically or by the mouth. Whiskey, in small amounts, was given to alcoholics and to the aged, if they bore it well. For extreme dilatation of the right ventricle, threatening disaster, venesection was believed to be indicated, and in one case (not in this series) he had resorted to it with good results. In this treatment not only was frequent or violent catharsis by such agents as calomel and salts avoided, but also excessive heart stimulation, especially with digitalis (which should never under any circumstances be given by the mouth), the use of analgesics or hypnotics of the coal tar class, the use of expectorants, intestinal antiseptic drugs, and diuretics, and the use of creosote carbonate quinine, hexamethylenamine, camphor, or any drug for a specific bactericidal effect. Anything like positive conclusions, he went on to say, could be properly drawn only from the statistics of a very large number of cases, and there were few diseases in regard to which it more became us to be reserved in this respect than pneumonia. But although the report of this series of cases might not serve as a basis for positive conclusions, it certainly was suggestive. Particularly suggestive were the following facts observed: (1) While in nearly one-third of the cases the temperature reached or exceeded 105° F., only one of the four deaths occurred among these patients. (2) The clinical observation was made in a number of instances that after a stage was reached where the circulatory signs and symptoms pointed to a speedy collapse, according to experience in the past with other methods of treatment, the heart showed an unusual endurance, which enabled it to keep on beating until the time of defervescence came, with recovery. (3) The systolic blood-pressure fell below the pulse rate in 27 out of 31 cases in which sphygmomanometric records were made, but out of those 27 cases which showed this supposedly bad prognostic sign, only 3 died, while 24 recovered. (4) Pronounced vasomotor paralysis did not develop in any of these patients after admission. (5) Tympanites in noticeable degree was not observed in any of the patients except those who entered the hospital with it, and in the latter, barring the two moribund cases, it soon decreased markedly or disappeared.

Dr. AUSTIN W. HOLLIS said he would be quite ashamed to compare his own statistics with those of Dr. Cornwall, although they were no worse than the average. The general mortality for large numbers was the same today that it was twenty years ago—between 20 and 25 per cent. When we took cognizance of the nature of pneumonia, and of the subjects most liable to the disease, the aged and cardiacs, cardionephritics, and alcoholics, we had to concede a mortality of 10 per cent. as inevitable. The severity of many of the cases outlined in the paper would not permit us to say that under any treatment the results would have been as favorable, and if we analyzed the main points which Dr. Cornwall inculcated we might find good reasons for his arguments. First, as to the diet: "Antiputrefactive" sounded well, but he felt bound to say that the ordinary diet employed generally in pneumonia, as milk, broths, gruels, and albumen water, had been found by long experience to be about the best for such a disease, and he did not think that Dr. Cornwall had really made any good points in the matter of

dietary. Second, as to letting the bowels alone and non-use of cathartics he quite agreed, for he believed that the initial calomel and continuous purgation often fatally disturbed digestion. Third, the avoidance of useless drugs and much alcohol was a most admirable practice. Fourth, as to the use of calcium salts. We could only theorize as to the possible effects of these salts in pneumonia. Dochez had found the coagulation time of the blood during the acute stage of the disease prolonged under their use, while Ewart had found it shortened. Again, Rudolph and Cole had found that calcium, administered by the mouth, had no effect on the coagulation time. Januseklie had shown that pleural effusions may be checked by subcutaneous injections of calcium chloride, and several observers had shown that the permeability of the vessels is lessened by the use of the calcium salts. Lauder Brunton had suggested the employment of calcium salts in pneumonia to neutralize the toxins of albumoses and peptones and to counterbalance the sodium chloride retention, and because of their direct stimulating effect upon the heart. We might assume that their use in this disease diminishes exudation and improves capillary tone, thus giving more power to the heart; but it would take a very large experience to prove that the mortality of pneumonia is lessened by them. While the mortality in the disease might not have materially decreased in the last twenty years, many advance steps had been taken which might pave the way for much better results. A few years ago the cold fresh air treatment had been heralded as a wonderful reducer of mortality, and it bade fair to delay our therapeutic resources in the same manner that tub bathing had done in typhoid fever. Cold air was of value in most cases, and fresh air in every case, but, after all, these were only hygienic necessities. As to chemotherapy, preparations of creosote were still held in repute as making the lungs a less favorable breeding place for the pneumococcus, and now camphor, supposed to have the same effect plus a stimulating action on the heart muscle, had taken a still greater hold on our imagination; but in watching individual cases he had never met with an appreciable response to their employment. Chemical bactericides such as ethylhydrocuprein, as experimentally tried on animals by Morgenroth, did not seem a promising discovery, as they were more likely to do harm than good to the host. In regard to drugs in general, those which affected the heart or blood-vessels had always been given a prominent place in the treatment of pneumonia, and definite knowledge concerning their value had accumulated. Aconite, nitroglycerin and other vasodilators, once so much used, had been abandoned as harmful. Preparations of digitalis, in his opinion, were equally harmful, save in exceptional instances. Strychnine and caffeine still retained their place as excellent transitory cardiac and vascular stimulants. Adrenalin, subcutaneously or intravenously, had proved its value as a heart stimulant and reducer of pulmonary congestion by dilatation of the coronary and bronchial arterioles. The greatest triumph that he had ever seen by drugs had been in the use of this agent in those trying cases of bronchopneumonia in infancy characterized by edematous lungs, fixed diaphragm, retracting airspaces, and pale purplish eyeballs. Two minims of adrenalin, hot mustard baths, and cool fresh air had in his experience pulled two such cases from the grave. Drugs which eased pain and cough and caused sleep must often be used. The best of these was codeine, and next came dionin or morphine. Paraldehyde intravenously was excellent in alcoholics, but the ordinary hypnotics of the veronal type, except in very small doses, were all pernicious. Bacterial vaccines, in doses of from ten to one hundred millions, had been very well tried. N. Rau, reporting 200 cases, with a mortality of 16 per cent., had seen no bad effects and believed the vaccines to be of positive value, especially when used early. His own experience was of the same favorable character, but he thought that in such a rapid disease their effect could hardly be striking. Antipneumococcus serum had been used by Roberts in lobar pneumonia and by Freeman in bronchopneumonia. From their reports, as well as his own experience, he did not think it of any value. Pneumococcus phylacogen was a double-edged sword, perhaps capable of killing the enemy, but a dangerous weapon to employ. We were not yet in possession of sufficient knowledge to advise its use during the acute stage, but, in his opinion, one of the greatest advances in the treatment of some of the phases of pneumonia was with this agent. Delayed resolution, abscess of the lung, necrosis, and subacute or chronic pneumococcic infections of the broncial or bronchopneumonia type would clear up in a marvelous manner under its employment. The initial dose, if given intravenously, should never exceed one-twentieth of a cubic centimeter.

Dr. CORNWALL said that while he had emphasized in the paper the point that no reliance ought to be placed on the statistics of such a small number of cases as that reported, it certainly seemed a significant fact that in the last forty hospital cases he had had previous to adopting the plan of treatment now described the mortality had amounted to 20 per cent. The good result met with in the present series of cases he attributed largely, first, to the system of diet employed, and, second, to the non-disturbance of the bowels. The whole idea was to make the metabolic burden as light as possible for the patient. He had laid stress upon exactness in prescribing the kind of diet and the times for giving the food, and this he considered as essential for the welfare of the patient as precision in the administration of drugs. He had also emphasized the importance of the salts in the diet, particularly the calcium salts. He could not agree with Dr. Hollis that there was no advantage in the dietary scheme which he had adopted over the diet usually employed in pneumonia, and too often given in a careless, haphazard way. As to chemotherapy, he had no faith whatever in its specific agency. In the whole range of medicine there was only one instance of a bacterial disease in which a chemical agent appeared to have any such effect—namely, syphilis—and here the result was apparently due to the fact that the diseased process was of such long duration.

A New Operative Treatment for Spastic Paralysis.—Dr. WILLIAM SHARPE said that spastic paralysis was a condition resulting from a lesion of the brain occurring before, during, or shortly after birth. It was characterized by more or less complete paralysis of the part affected, and was associated with a stiffness or spasticity, the degree of which depended on the extent of the involvement of the pyramidal tract. This hypertonicity produced muscular contractures and deformities, usually flexor in type, with a corresponding over-stretching of the opposing muscular groups. In mild cases, however, the spasticity might be very slight. Frequently athetoid movements of the limbs were observed, and epileptiform attacks might occur. In a large proportion of the cases, as the child grew older, not only did the spasticity and its resulting contractures increase, but the mentality became impaired, and this was likely to eventuate in imbecility or even idiocy. The most common cerebral lesion was intracranial hemorrhage which caused a clot to form over the cortex, and, according to the extent of this, and the pressure produced, did we find the gravity of the clinical signs. In spastic paralysis the hemorrhagic lesions constituted 70 per cent. of the cases, the remaining 30 per cent. being mostly the result of agenesis and maldevelopment and of meningoencephalitis complicating acute infectious diseases. The operations which had been used in the past, and were still being employed, to improve the conditions of spastic paralysis, such as tenotomies, tendon lengthenings, sections of the posterior spinal nerve-roots, nerve sections, and alcohol injections of peripheral nerves, were, in the speaker's opinion, of only temporary benefit, and he had yet to see a case in which the spasticity had not returned, at least to some extent, within one year. Little, if anything, had been done to permanently improve these conditions, and he now offered his observations in the hope that they might lead to a more satisfactory treatment of these pitiful cases. His attention had been first centered on the importance of relieving the increased intracranial pressure, as a means of lessening the spasticity and improving the mentality in such cases, by a decompression operation performed at the Nassau Hospital in June, 1913. In all his work Dr. Benjamin Farrell had been associated with him. Since then they had done a subtemporal decompression in 24 selected cases, and the results had been so gratifying that they felt justified in making a report of what had been done up to the present time. In all the cases practically the same improvement had been noted, and while, on account of the short time since the operations, they would not assert that such improvement would be permanent, they could see no reason why the improvement should not become more and more marked as the children grew older. They had selected for operation only the extreme types of spastic paralysis. In cases of the hemiplegic, paraplegic, or diplegic type, with a definite history of difficult labor, in which, on ophthalmoscopic

examination, signs of intracranial pressure were shown in the dilated retinal veins and a blurring of the optic disks, especially in their nasal halves, a large right subtemporal decompression was performed for the purpose of relieving this pressure. If the pressure were extremely high and remained high after the operation, a left subtemporal decompression was done the following month, the operative recovery requiring only a week or ten days. The usual pathological findings were definite cystic formations resulting from a cortical hemorrhage occurring at birth. The after-treatment consisted in the corrections of deformities by tendon lengthenings or stretchings of the contractured muscles, the maintenance of corrected positions by suitable braces, and skilled massage in conjunction with electricity; particular attention being given to the weakened and overstrained muscle groups. A systematic course of muscle training was carried on daily. The improvement had been so marked—not only a diminution of the spasticity, but a definite amelioration of the mental condition—that they believed a cranial decompression was indicated in such cases of spastic paralysis as showed intracranial pressure on ophthalmoscopic examination. The operation was not a formidable one in the hands of one trained in neurological surgery, and they had had no deaths. It was a matter of importance that the anesthetic should be administered by an expert. One of the great advantages of this method was that, on account of the improved mentality resulting from the operation, the cooperation of the patient was obtained in carrying out the after-treatment. Of all the cases of spastic paralysis examined by them about 60 per cent. had shown signs of intracranial pressure, and were, therefore, cases which, in their opinion, could be greatly improved. Cases due to agenesis and maldevelopment of the cortex, not, of course, showing signs of increased intracranial pressure, were easily excluded by an ophthalmoscopic examination. In connection with the paper eight children were shown upon whom the decompression operation had been performed.

Dr. Benjamin Farrell made some remarks in further explanation of the after-treatment, and confirmed Dr. Sharpe's statements in regard to the gratifying mental improvement in the cases.

Dr. William M. Leszynsky said that the enthusiasm and hopefulness as to cure in these cases of infantile cerebral palsy were not justified by the facts, and were based upon an erroneous assumption as to the underlying condition of the brain. Dr. Sharpe had qualified his remarks by stating that the operation of subtemporal decompression was performed only in those cases in which "pressure upon the brain was shown by ophthalmoscopic examination." He (Dr. Leszynsky) felt confident, however, that upon further investigation the patients exhibited would not come up to the required standard, as claimed, when subjected to a critical neurological analysis. It was true that the spastic hemiplegia was the direct result of meningeal or cortical hemorrhage over the Rolandic area, but the presence of a cyst was secondary to the hemorrhage, being merely a terminal condition. The paralysis, due to damage to the pyramidal tract usually followed by secondary degeneration, was present for some time prior to cyst formation, and it was entirely unwarranted to assume that pressure from such a cyst was an important etiological factor in relation to the paralysis. Hence, there was no rational indication for removing a portion of the skull for the relief of supposed intracranial pressure. He recalled that about twenty years ago the Lannelongue operation was in vogue. This consisted in making longitudinal furrows in the skull about one inch wide and several inches in length, in both parietal regions, and was based upon the false idea that a normal brain was prevented from proper growth and expansion on account of premature cranial synostosis. The procedure was abandoned, as it failed to accomplish the desired results, and it was soon demonstrated conclusively that we were primarily dealing with a defective brain. Dr. Sharpe decried all other forms of treatment in these cases, as being directed only to peripheral conditions and not to the source of the trouble, but admitted that the desired improvement required the aid of just such measures subsequent to the cranial operation. As to the alleged mental improvement, it seemed to him that this was but temporary and the result of environmental changes, and largely a matter of self-deception on the part of the mother. A similar state of affairs occurred at the time of the vogue of the Lannelongue operation. It was but a repetition of history. Dr. Leszynsky protested against this surgical plan of treatment in these cases as being illogical and unsupported by a sound pathological foundation. The reader of the paper, he thought, had in his surgical ardor permitted himself to be deceived.

Dr. Edward Wallace Lee told of the case of a young woman of nineteen with spastic paralysis who had been treated for epilepsy, upon whom he had done a decompression with good results. After the operation the patient's mental condition, which had been that of a child of twelve years, improved, the spasms ceased, and the paralysis was markedly relieved.

Dr. Sharpe, in closing, said that the keynote regarding operation, it seemed to him, was the proper selection of cases. There were two reasons why in the past cranial operations had failed in these cases: First, there had been no selection of cases according to the presence or absence of intracranial pressure. If there were no increased pressure, naturally an operation would be of no benefit whatever. Second, the operations in the past had been of the typical bone-flap character; after the exposing of the brain the flap was replaced, and, naturally, no improvement had resulted because the intracranial pressure had not been relieved. A careful selection of cases was necessary, and also the inclusion in the operation of a permanent removal of bone. All the patients shown had had orthopedic treatment previous to the operation, without any real benefit. He had had a series of motion pictures taken before and after operation which showed the marked improvement in these cases. As to the pathology of the condition, if the hemorrhage were within the cortex, the brain would be permanently damaged, but if this were not the case the cortex would be damaged only by the pressure upon it. In the latter instance a cyst developed, and all that we did was to offset the effects of the pressure of this cystic formation. It seemed to him that if we were to adopt an attitude of hopelessness no progress would ever be made.

NEW YORK ACADEMY OF MEDICINE.

Section on Obstetrics and Gynecology.

Stated Meeting, Held April 21, 1914.

Dr. Asa B. Davis in the Chair.

Adhesions of the Sigmoid Flexure of the Colon with Report of Three Cases.—Dr. James N. West reported these three cases which presented very different pathological conditions, but they had one feature in common which had caused him to think of them in one group. This feature was adhesions of the sigmoid which were incidentally released and which in being released gave relief to the most prominent symptoms. The first case was that of a woman thirty-three years of age, never pregnant, who was operated on for an ovarian tumor of the left side. During the operation Dr. West had observed and called attention to several minute whitish spots on the peritoneum of the broad ligament, the intestines, and the uterus. The chief features of interest in this case were: 1. The rapid development of carcinoma from these few almost microscopical foci. 2. The chief early symptoms came from a band across the sigmoid flexure. 3. Rapid improvement after the removal of the obstructive band, notwithstanding the coincident development of carcinoma. 4. The presence in the region of obstruction of a movable and varying tumor. The second case was that of a woman, twenty-six years of age, who had been married at the age of nineteen and had had one pregnancy in which abortion was induced at two months. She had been operated on for appendicitis four months before marriage, the operation being followed by an abscess which opened through the appendicitis incision. She had also had the left ovary removed and later had a curettage. She then had a lipoma of the right breast removed and then the right ovary, and also an operation for the removal of adhesions. She then appeared complaining of pain in the left side of the pelvis, severe constipation, headaches, sleeplessness and extreme nervousness. A mass the size of a small orange could be felt in the left side of the pelvis and a swelling could be observed in the iliac region. A diagnosis was made of intraligamentary cyst of the left side and intestinal adhesions. At operation extensive adhesions of the omentum and intestines were encountered and were with difficulty separated. The sigmoid flexure was found to be somewhat twisted on itself and firmly adherent to the anterior brim of the pelvis and abdominal wall. The chief feature in this case was the marked relief from pain

and the resumption of normal function of the bowels after release of the sigmoid adhesions. The third case, a woman twenty-five years of age, entered Dr. West's service at the Post-Graduate Hospital in November, 1913. She had been regarded as a neurasthenic and almost a drug habitué. She complained of pain in the left lower quadrant which had been present for five years. She was subject to attacks of rapid convulsive movements of the abdominal muscles and diaphragm, which would continue until a drug was administered. The woman had had eight operations. A diagnosis of salpingo-oophritis and intestinal adhesions was made. At operation the intestinal adhesions were freed and the sigmoid flexure was obsrved with a band across its lower part, almost obstructing it. The band was thoroughly dissected away. The chief points of interest in this case were: 1. The patient had been regarded as a neurasthenic and had been repeatedly told that her pain was imaginary and the convulsive attacks hysterical. 2. There was a phantom tumor present at times, and the pain always proceeded from that point. 3. Uncertainty of the diagnosis and the relief following the operation.

Amenorrhea Primitiva.—Dr. IRA B. TERRY reported this case. The patient was a woman, twenty-seven years of age, who was first seen at Dr. West's Clinic at the Post-Graduate Hospital, November 13, 1913. She was an Italian who had been in this country four years. Her family history was good and she had a sister who was married and had three children. The patient had been married seven years and had never menstruated. She gave a history of pain in the left iliac region which came on once a month regularly and lasted two or three days; this would come on regularly for five or six months and then would cease for that length of time. The vaginal examination showed a cervix slightly larger than normal, and hard. The uterus was small, firm, and regular. The ovary on the left side was larger than normal, and a distinct corpus luteum could be felt on it. The other ovary was not freely movable and the tubes were palpable. The patient had no vicarious menstruation. The Wassermann was negative. She was treated by the administration of ovarian extract and calcium lactate, and also small doses of thyroid, but with no effect. She was then given extract of corpus luteum of pregnant cows with suprarenal extract, and lastly an ampoule of extract of pituitary body twice a week. When he started with the first treatment the patient had severe cramp-like pains in the lower part of the abdomen typical of dysmenorrhea and had to stay in bed for three days. She was given ergot-apiol capsules to relieve the pain. Each month, just as it was time for her to have these pains the left ovary would be as large as a hen's egg; then about the middle of the month it would be down to the size of an English walnut again. It was possible that there was an obliteration of the uterine venous plexus.

Dr. JAMES N. WEST asked Dr. Terry if he had had any experience with the use of animal extracts in these cases of amenorrhea primitiva. He had used them in several cases. He had employed the corpus luteum of the cow, and believed that he obtained good results, as the patient seemed to menstruate better than before its use.

Dr. HERMAN J. BOLDT said that in his experience he had seen no benefit from the use of the animal extracts. He had used an extract of the interior lobe of the pituitary body in these cases of amenorrhea primitiva, but the results were negative.

Result of Goffe's Operation for Complete Prolapse.—Dr. GEORGE GRAY WARD, Jr., presented this patient, a woman, thirty-four years of age, who for two years prior to the time he had operated on her had had a complete prolapse, the uterus and both vaginal walls hanging outside the vulva. He had operated on her two years and seven months ago. She was presented to show what results could be obtained in these difficult cases.

Dr. WARD asked the chairman to appoint a committee of three to report on the present condition of this patient. As he had done the Goffe operation he requested that Dr. Goffe might be appointed on the committee.

Dr. ASA B. DAVIS appointed Dr. Goffe, Dr. Boldt and Dr. West on this committee.

Dr. J. RIDDLE GOFFE said that he doubted if any could realize without seeing her the condition formerly presented by this woman. Now the levator ani muscles were very firmly united and the support to the pelvic floor was simply perfect. The vagina was rather small in size but not too small. In examining the woman he had detected a broad, firm band of tissue passing across the pelvis, evidently the broad ligaments which were sewn together in the median line. The comforting thought was that while extreme procidentias had been the *bête noir* of the profession, now they had an operation that would stand the test of time. Dr. Goffe congratulated Dr. Ward on the result that he had obtained in this particular case.

Dr. HERMAN J. BOLDT said he was in accord with what Dr. Goffe has said regarding the result of this operation for complete prolapse. He could not imagine it possible for anyone to get a better result than they had found in the examination of Dr. Ward's patient.

Dr. JAMES N. WEST said that his examination of Dr. Ward's patient confirmed all that he had said regarding the result of Goffe's operation for complete prolapse. He did not think that the patient would be troubled with either rectocele or cystocele. He had always felt some hesitancy in doing a hysterectomy in a patient of thirty-four years or thereabouts, but he should not hesitate to remove the uterus in such a case as this one. One could not ask for better results by the Goffe operation than were shown in this case.

Dr. GEORGE GRAY WARD said the question of what was the best operation in cases of complete prolapse was always before them. Recently, while in Rochester, Minn., he had seen the Mayos operate for complete prolapse and they did a combination of the Goffe operation and the Watkins-Duhrssen. They first removed the uterus and sutured the broad ligaments together as Goffe did and then they interposed the broad ligament between the bladder and vagina, anteverting the broad ligament and placing the bladder on top of it. He had tried this operation recently but did not yet know just what the results would be. This certainly was a promising operation and worth a thorough trial.

Report of a Case of Vesicovaginal Fistula with Unusual Phosphatic Deposit.—Dr. GEORGE GRAY WARD, JR., reported this case. The patient was a woman, forty-four years of age, who had had a very stormy history. Nine years ago she had undergone a very difficult labor. At that time he had used the Tarnier forceps, to which he seldom resorted. In this case they slipped and the result was a vesicovaginal fistula. This was repaired shortly after labor and with apparently a perfect result. Last May she returned and a mass was found encysted in the anterior vaginal wall; this was about the size of a cherry, and was undoubtedly made up of phosphatic deposit from the urine. She developed a leak in the anterior wall beneath the phosphatic deposit. He made a longitudinal incision of the vaginal wall and dissected it freely from the base of the bladder and thus removed the deposit with its sac. The opening was very minute so that he could scarcely pass a bristle through it. There was a small opening in the vaginal wall into the encysted deposit. The cystoscope had previously revealed the opening in the trigone. The bladder and vagina were sutured separately and the patient made a complete recovery.

Specimens from Two Cases of Carcinoma Uteri Obtained by the Wertheim's Operation.—Dr. GEORGE GRAY WARD, JR., made this presentation. The history of the first patient, he said, was of unusual interest. She was forty-two years of age, and had had seventeen children, the last ten months ago. Since that time she had been bleeding profusely and she still had a foul discharge. He did a typical Wertheim operation. The enucleation was satisfactory so far as the uterus was concerned, but it was found that the growth had eaten into the bladder. The case looked hopeless, but being encouraged to go ahead he removed a good part of the vagina and parametric tissue and a suprapubic cystotomy, as he found the growth perforating the trigone. A section of the bladder nearly the size of a twenty-five cent piece was removed. An elliptical incision was made in this removal. The drainage employed was that used after the operation of suprapublic cystotomy. There was no leakage from the bladder for six months. The patient had not lost weight and felt well. Recently there had been some bleeding on coitus and examination revealed a small polypoid mass in the vaginal scar. This was removed and sent to the pathologist, who found no evidences of malignancy.

Dr. WILLIAM MCKIMMIE HIGGINS reported on the small polyp. The diagnosis was vascular fibrous polyp with secondary simple chronic inflammation.

Dr. GEORGE GRAY WARD presented a second specimen of carcinomatous uterus removed by the Wertheim

operation about six weeks ago. The patient was forty-seven years of age, a widow, and the mother of four or five children. Her symptoms had progressed for a year. In this instance he removed about one-half the vagina as well as the parametric tissue as shown in the specimen. The interesting point in this case was that the patient's blood was low in hemoglobin, and they had been able to help her by transfusion of blood from a vigorous son. Dr. Edward Peterson did the transfusion by the Linderman method. The patient felt much better even on the following day. This was a recent case but it was interesting because of the marked degree of anemia complicating it.

Dr. Ward presented another specimen showing the result of the Wertheim operation which had been removed from a patient last December. The patient was thirty-eight years of age, and had had three children. She had had menorrhagia for about a year. The parametrium and the amount of vagina removed was shown in the specimen. There was no sign of recurrence up to the present time, four months after the operation.

Dr. Herman J. Boldt said that Dr. Ward was to be congratulated on the results obtained in his first case of carcinoma, particularly in the case of such marked obesity.

Dr. J. Riddle Goffe said he thought Dr. Ward very fortunate in obtaining such good results in his case of carcinoma, and he was to be especially congratulated on the case with the very low percentage of hemoglobin. The case recalled one that he had seen at the Woman's Hospital two years ago. She was brought in on a mattress, the bleeding having been terrible and continuous for weeks. He found the uterus large and made the diagnosis of some fibroid condition, probably submucoid fibroid. He made a short incision through the vaginal wall on either side, and applied compression forceps, catching the uterine arteries and controlling the bleeding. A month later he did a vaginal hysterectomy. On opening the uterus he found the interior full of irregular stalactites, protruding into the cavity of the uterus. Laboratory examination showed this to be carcinoma (epithelioma). He did not do the extreme operation. The woman improved rapidly and went home. She came back to his office in October, looking strong and healthy, but he found the pelvis filled with recurrences.

Dr. Herman J. Boldt said it seemed remarkable how long the first patient had had symptoms before the disease causing them became known. She had symptoms of carcinoma of the cervix for seven months and the disease was strictly limited to the cervix and did not extend beyond at all.

Dr. Charles Gordon Heyd said that in this case it was a comparatively easy matter to do the bladder operation if one had recourse to a distinct bladder technique. The Wertheim operation was abandoned for the time being and the bladder opened suprapubically in the space of Retzius. A wide excision *en masse* was made and the vesical defect closed after an ordinary suture method with No. 2 chromic catgut. Drainage was established by means of an independent stab wound anterior to the suture line. The reposition of the peritoneum over the posterior surface of the bladder adequately prevented leaking and the postoperative course was uneventful. The case showed how readily vesical carcinoma might be attacked and the high reparative power of the bladder in the face of a marked carcinomatous invasion.

Dr. George Gray Ward, Jr., said that in answer to Dr. Freidman's query as to whether the glands were removed, "yes." In all the cases they looked for the enlarged glands and removed all they could find.

External Rupture of Broad Ligament Hematoma.—Dr. Thomas A. Cherry reported this case, which occurred in the outdoor obstetrical service of the Post-Graduate Hospital. The patient was 38 years of age. She had had two stillbirths and a miscarriage and was obese, with large relaxed abdomen. She came to labor somewhat over term. The first stage was normal, but during the second stage the force and frequency of the pains subsided and the use of the forceps was indicated. The solid blade forceps were tried, but the second blade could not be rotated opposite the first posterior blade. Change was made to the axis traction instrument. Difficulty was encountered in applying these and traction had to be made with the blades in the oblique application. As the head appeared on the perineum and further traction was exerted a gush of dark blood was propelled with great force from the introitus. After this apparent rupture of some structure the head was easily delivered. The child was moderately asphyxiated, but cried on spanking. On seeking the origin of the hemorrhage a vertical laceration about three cm. in length was found at the upper angle of the anterior and left vaginal walls and labium minus close to the pubic ramus from which slight oozing of blood was seen. On exploration the rupture was found to lead into the cellular tissue outside the vaginal wall and into a cavity extending upward alongside the cervix and lower uterine segment and base of the left broad ligament about twelve cm. from the vulva. On further examination the finger came into contact below with the posterior surface of the pubis and anteriorly in the median line with the neck of the bladder. The uterus and bladder were found intact. The patient being in considerable shock the cavity was packed with gauze and efforts were made to combat the shock. The packing was partly removed on the third day and completely on the fifth. The cavity gradually filled in and was entirely healed on the twelfth day postpartum. The child developed stupor and refused to nurse on the third day. Spasm of the lips and eyelid, and later nystagmus followed, and death ensued on the fifth day, apparently from meningeal hemorrhage. The unusual condition of the mother was evidently an unrecognized pelvic hematoma formed during the first stage of labor in the cellular tissue at the base of the broad ligament, subperitoneally and above the pelvic fascia. As forcible traction was exerted on the head it dissected its way through the cellular tissue, and reaching the pubic ramus was deflected laterally until arrested by the hematoma which was forced toward the median line, where it was arrested by the anterior ligaments of the bladder. The strong fascia of the levator ani muscle prevented it making its way posteriorly, so being forced down by the advancing head rupture externally occurred through the inferior triangular ligament under the descending ramus of the pubis. Dr. Williams of Baltimore had collected 33 cases of subperitoneal hematoma, including one of his own, and since then others had been added. In the majority of the cases the hematoma became apparent following delivery, and thus far he had not ascertained that any had complicated the second stage of labor.

Specimens Showing Different Stages of Renal Tuberculosis.—Dr. Henry Dawson Furniss presented ten specimens and reported the histories of the cases from which they were taken. In a number of the cases the tuberculosis was secondary to infection elsewhere in the body. In several of the cases a tuberculous fistula persisted for a longer or shorter period following the operation. There had been but one death in the series.

Exceptionally Rapid Manifestation of Sepsis Following Curetting after Spontaneous Abortion.—Dr. Herman J. Boldt reported this case. The patient was a woman, 23 years of age, who aborted spontaneously at about the eighth week of her first pregnancy. Dr. Boldt had seen the patient in consultation on the following day because of some bleeding and the supposition that the abortion was incomplete. She was curetted at about 11 o'clock in the forenoon and the following afternoon she had a chill and her temperature began to rise, reaching 103.4° F. Her pulse was 140. She was transferred to the hospital, the uterine cavity irrigated with iodine water, and the cul-de-sac extensively opened and packed with iodoform gauze. Bacteriological examination showed a streptococcic infection. General peritonitis followed and death occurred on the third day.

Large Abdominal Wall Abscess of Unknown Origin.—Dr. Herman J. Boldt reported this case, which occurred in a patient who was five months pregnant for the third time. For three weeks she had had fever and at times was chilly. Examination revealed a hard mass in the abdomen about five inches in diameter in every direction. It involved only the parietes and though painful to pressure showed no fluctuation. On opening it about one hundred c.c. of foul pus escaped. No foreign substance was found in it. The walls of the abscess were about one inch thick and edematous. Bacteriological examination showed non-hemolytic streptococci in short chains. No other microorganisms were found.

Myofibroma.—Dr. Herman J. Boldt reported four cases of myofibroma, all having the usual history of profuse bleeding. The first patient had evidences of cardiac changes caused by the bleeding, the blood pressure being 80 on the diastole and 140 on the systole. There was also a very sensitive area at the junction of the second sternocostal cartilage junction and another at the base. The second patient had a blood pressure of 160 on the diastole, but no cardiac changes

were ascertainable. The third patient suffered from most severe headaches, which ceased after the operation. The connection between the bleeding and the headaches, which always occurred about a week before the severe bleeding, Dr. Boldt said he could not explain. The fourth patient who had bled profusely for three years at intervals of three or four weeks, had a uterus three or four times the normal size. It was removed by the vaginal route. Microscopical examination showed a marked increase of fibrous connective tissue without increase in the muscular elements. The walls of the blood vessels were markedly thickened.

Large Hydrosalpinx Which Caused an Erroneous Diagnosis.—Dr. HERMAN J. BOLDT reported this case in which all the evidence pointed to a diagnosis of ovarian cyst. At operation, however, it was shown that they were dealing with a large hydrosalpinx. If this diagnosis had been correctly made the distended tube would have been excised by the vaginal route and drained, since the fluid in such cases was not obnoxious.

Carcinomatous Uterus Removed by Radical Abdominal Operation.—Dr. HERMAN J. BOLDT reported this case. There were no glandular enlargements and the lateral walls of the cervix showed no evidence of the disease having gone outside the boundaries of the uterus. The history of the case was such as to have led one to expect a much more extended involvement.

Case Histories Illustrating Intestinal Complications of the Puerperium.—Dr. HENRY P. DEFOREST said we were in the habit of regarding intestinal complications as essentially medical in character, but occasionally surgical conditions arose which might be followed by serious and even fatal results. The diagnosis in such cases was by no means easy, and it was surprising what nature unassisted by a physician might effect in the way of a cure. In illustration of this statement he cited the case of a woman, 34 years of age, in her first pregnancy, who was attacked with nausea, vomiting, and pain in the right iliac fossa, about seven weeks before labor was expected. She later noticed black spots before her eyes and was troubled with dizziness. Under restricted diet her symptoms abated, but recurred later. There was very little albumen in the urine. As she grew worse it was decided a few days before labor was expected to terminate the pregnancy. This was done. The child was extracted by version, and, though still living, had had a number of convulsions during the first month of life, the cause of which was never apparent, though it seemed probable that they were due to toxic conditions arising from maternal causes. After labor a large tumor mass was found in the right iliac region, corresponding to the position of the ascending colon. This mass changed its position and the patient's temperature showed wide ranges from 97.5° to 106° F. in twenty-four hours. On the fifteenth day she experienced some unusual sensations in the epigastric region, the tumor suddenly disappearing. A few hours later she passed by rectum a piece of small intestine about ten inches long, quite black, and gangrenous. Evidently some weeks previously when she felt something giving away in the right iliac region an invagination of the small intestine through the ileocecal valve had taken place, and this had progressed along the transverse colon until the pressure had shut off the circulation in the invaginated portion and sloughing had occurred. The patient's temperature steadily rose for a week and then spontaneous healing must have taken place for the patient made an uneventful recovery.

A second complication of puerperium was constipation. A large number of women troubled with habitual constipation found this symptom exaggerated during the puerperium. The temperature in such cases was often indicative of the condition unless infection of the birth canal was coexistent. In such cases an accurate diagnosis must often be reached by exclusion. Dr. De Forest cited illustrative cases and stated that the following formula was one of the best for the speedy and thorough evacuation of the bowels: Oleii tiglii, ♏ ¼; oleii anisi, ♏½; oleii ricini, ♏ xx, one capsule. Four of these capsules usually caused watery catharsis without griping in from thirty to sixty minutes.

Dr. DE FOREST cited a case illustrating the puerperium complicated by gastritis, and one in which it was complicated by typhoid fever. He said that it occasionally happened that delivery took place during the progress of typhoid fever and it was a matter of some interest to know whether the occurrence of labor under such conditions added materially to the inherent dangers of the intermittent disease, or whether, on the other hand, the constitutional toxemia which occurred with typhoid fever influenced the morbidity of a woman during the puerperium. In the case cited the convalescence was uneventful and both mother and child did well.

The writer related the history of a case in which the puerperium was complicated by general enteritis due to the *Bacillus coli communis*. This was followed after about two weeks by an infectious neuritis of the right anterior crural nerve. It was his belief that owing to the intestinal condition the infection had its origin in the colon bacilli. A vaccine of this organism was administered, fifty million the first day, one hundred million the second day, and four million on the fourth. An enema was given daily and globules of ten drops of castor oil, containing one-eighth of a grain of podophyllin were administered to increase the secretion of the bile and to favor intestinal antisepsis. The patient gradually recovered. Occurring at the time it did the differential diagnosis between this condition and phlegmasia alba dolens was of practical importance. Finally Dr. DeForest cited a case of the puerperium complicated by intestinal parasites in which for eleven days the cause of the temperature was in doubt. Finally the finding of lumbricoid worms gave the clue to the treatment and the administration of anthelmintics was followed by a clearing up of the symptoms. A similar case had been reported by Hirst, in which a large tape worm was found to be the source of the trouble.

Case of Osteitis Deformans.—B. Myers reports the case of a man, aged 57, who came to the Western General Dispensary about a year ago for advice with regard to severe pains in the back and legs. It appeared that he had suffered from pains in various bones and joints for five years. The infected bones included the vertebræ, both femora, especially the left, both tibiæ and fibulæ, the right radius and ulna, and the skull. Tho walk of the patient was suggestive of osteitis deformans. He had lost about four or five inches in height since his pains began. The head was bent forward, evidently on account of the usual dorsocervical kyphosis of this complaint. There was very distinct thickening of the left femur, which also showed an outward and a forward curve. There was some thickening of the left tibia and perhaps the right radius and ulna. The clavicles seemed to be a little enlarged also. The peculiar feature of the case was the apparent want of increase in thickness of the cranial bones. The patient could wear the same hard hats now as formerly. He had arteriosclerosis rather well marked. Pains in the precordial region troubled him occasionally. The appetite was good, the bowels were open daily, the speech was "stuttery" at times, the memory fair, and he slept well. There was no similar case in his family. The urine was normal. The calcium content of his blood was estimated upon two occasions, and each time it was less than normal. The Wassermann test was negative. The diagnosis of osteitis deformans was backed up by the *x*-ray photographs, the only difficulty being his skull and a rather prominent lower jaw. The latter suggested the possibility of the co-existence of Paget's disease with acromegaly, but an *x*-ray picture showed a normal sella turcica and nothing abnormal in the inferior maxilla. With regard to treatment, he had taken quinine, iodide of potassium, and nux vomica with no noticeable benefit. For the pain various liniments had been tried, and perhaps had been of some use, but the greatest relief from pain had been obtained from salicylate of sodium, which the patient was still taking in conjunction with tonics.—*Proceedings of the Royal Society of Medicine.*

Glioma of the Cerebellum; Recovery after Simple Drainage of Cyst.—F. E. Batten reports the case of a girl, aged 8 years, who in November, 1911, complained of headache, attacks of vomiting, and unsteady gait, which she had had for two months. On examination she had double optic neuritis and symptoms pointing to a tumor of the cerebellum, the ataxia being rather more marked on the right than the left side. A subtentorial decompression was performed on November 14 and a cyst containing a yellow fluid, which rapidly clotted, was found in the left lateral lobe. The wall of the cyst was formed of a new growth which infiltrated the lobe of the cerebellum. A small piece of the growth was removed and on microscopical examination showed the appearance of a glioma. The child slowly recovered, and now, two years later, seems quite well.—*Proceedings of the Royal Society of Medicine.*

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

The Ready Reference Hand-Book of Diseases of the Skin. By George Thomas Jackson, M.D. Seventh edition, thoroughly revised. Illustrated; cloth; 770 pages. Lea & Febiger, New York and Philadelphia.

A Synopsis of Surgery. By Ernest W. Hey Groves, M.S., M.D., B.Sc., F.R.C.S. Cloth; price, $3.25 net; 599 pages. William Wood & Company, New York.

The Surgery of the Stomach. By Herbert J. Paterson, M.A., M.C., M.B., F.R.C.S. New and revised edition. Cloth; 342 pages; price, $4.00 net; illustrated. William Wood & Company, New York.

Plain Rules for the use of Tuberculin. By R. Allan Bennett, M.B. Cloth; price, $1.00 net; 48 pages. William Wood & Company, New York.

Renal Diagnosis in Medicine and Surgery. By Dr. Victor Blum. English Translation by Wilfred B. Christopherson. Cloth; price, $2.00 net; 144 pages; illustrated. William Wood & Company, New York.

Tropical Medicine and Hygiene. By C. W. Daniels, M.B., F.R.C.P.; with a chapter on Snakes by A. Alcock, C.I.E., M.B., F.R.S., Lt., I.M.S. In three parts; well colored and other illustrations. Part II. Diseases due to the Metazoa. Second edition; cloth; price, $3.00 net; 278 pages. William Wood & Company, New York.

The Road to a Healthy Old Age. By Thomas Bodley Scott. Cloth; price, $1.00 net; 104 pages. Paul B. Hoeber, New York.

Health Through Diet. By Kenneth G. Haig, L.R.C.P., M.R.C.S., with the advice and assistance of Alexander Haig, M.A., M.D. Cloth; price, $1.25 net; 227 pages. J. B. Lippincott Company, Philadelphia.

Des Haarschwunds Ursachen und Behandlung. By Dr. S. Jessner. Paper; price M. 90; 50 pages. Curt Kabitzsch, Wurzburg.

Defensive Ferments of the Animal Organism. By Emil Abderhalden. Third enlarged edition; cloth; not illustrated; 242 pp.; $2.75 net. Wm. Wood & Co., publisher.

Text Book of Local Anaesthesia. By Prof. Dr. Georg Hirschel. Cloth; illustrated; 181 pp.; $2.75 net. Wm. Wood & Co., publisher.

Über die Ernährung des Auges. By Dr. med. C. Hamburger. Paper; illustrated; 117 pp. Georg Thieme, publisher.

Der Salvarsantod. By Dr. Carl Schindler, Spezialarzt für Hautkrankheiten in Berlin. Paper; illustrated; 184 pp.; price, 8.50 marks.

Proceedings (Transactions) of the Am. Medico-Psychological Assn., at the sixty-ninth annual meeting held in Niagara Falls, Canada, June 10-13, 1913. Cloth; illustrated; 462 pp. American Medico-Psychological Assn., publishers, 1913.

Die Entstehung und Behandlung der Karzinome. By Hofrat Dr. A. Theilhaber in München. Paper; illustrated; 182 pp.; 12 marks. Verlag von S. Karger.

Bakteriologische Untersuchungen. By Dr. Maunu af Heurlin, Assistenzarzt der Klinik. Paper; illustrated; 616 pp.; 12 marks. Verlag von S. Karger.

Lehrbuch der Psychiatrischen Diagnostik. By Privatdozent Dr. Adalbert Gregor. Paper; illustrated; 240 pp.; 4.80 marks. Verlag von S. Karger.

Diagnostik der Nervenkrankheiten, by Prof. Dr. Alexander Margulies in Prag. Paper; illustrated; 124 pp.; 3 marks. Verlag von S. Karger.

Das Ulcus Duodeni. By Dr. J. Schrijver. Paper illustrated; 184 pp.; 10 marks, gbsk 11.20. Verlag von S. Karger.

Modern Medicine. By Osler & McCrae. Cloth; illustrated; second edition.; 1,040 pages. Published by Lea & Febiger.

Religion and Drink. By E. A. Wasson, Ph.D. Cloth; 297 pages. Published by New York Printing House.

Abdominal Surgery. By Thorkild Rovsing, M.D. Cloth; illustrated; 471 pages. Published by L. B. Lippincott Company.

Therapeutic Hints.

Tincture of Iodine and Ichthyol in the Treatment of Furuncles.—M. Berger details this method of treatment as follows: In the case of soft furuncles, these are painted with tincture of iodine, and then covered with a 10 per cent. ichthyol ointment. When pointing occurs the pus is evacuated and the surrounding skin is cleansed with benzine in order that fatty substances may be removed. The tincture of iodine is again painted on and the ichthyol ointment is again applied. As soon as suppuration has ceased the use of the iodine is discontinued, and applications of pure ichthyol are now made. Finally, if an extensive raw surface is left, the following ointment should be applied:

℞ Nitrate of silver, 1 gram.
Balsam of Peru, 5 grams.
Lanolin, 100 grams.

In the case of hard furuncles it is necessary to persist in the application of tincture of iodine, followed by that of pure ichthyol. The latter may be allowed to dry on, and may be left exposed, or may be covered by a compress of gauze. The following day the ichthyol is washed off with hot water and the application of iodine and then of ichthyol is repeated. This procedure is repeated from day to day.. When suppuration occurs and drainage is effected, the use of the tincture of iodine is discontinued, but that of the pure ichthyol is kept up.—*Medizinische Klinik.*

Sodium Bromide in Gastric Therapeutics.—M. G. Leven extols the value of sodium bromide in the treatment of diseases of the stomach. With or without the addition of subcarbonate of bismuth sodium bromide is useful in sensory, motor, and secretory disturbances of the stomach which are not controlled by dietetic measures. The author prescribes sodium bromide in those cases in which alkalies, belladonna, and opiates are frequently used. The drug is of eminent value in the treatment of hypersecretion, spasm of the cardia or pylorus, and the various ill effects of aerophagia. Sodium bromide is used in preference to the other bromine compounds in the following prescription:

℞ Sodium bromide, 20 grams.
Sterilized distilled water, 300 grams.

One tablespoonful of this solution is given morning and evening, the dose being 1 gram of the salt. The remedy is to be taken one-half hour before meals in one-half glassful of water.—*Bulletin Général de Thérapeutique.*

The Synthetic Derivatives of Strychnine.—M. J. Chevalier states that a number of these derivatives have been produced by the processes of oxidation, reduction, and the addition of sidechains. These derivatives mask or completely abolish the excitatory action of strychnine upon the spinal cord, modify the cardiovascular effects of this alkaloid, and greatly diminish its toxicity. The ethylbetaine of strychnic acid is a good example of the above derivatives. Its toxicity is one-tenth that of strychnine. In nontoxic doses administered to warm-blooded animals its excitatory action is relatively slight. In frogs large doses cause a paralysis analogous to that produced by curare. The ethylbetaine of strychnine acid is a depressant to the cardiovascular system.—*Bulletin Général de Thérapeutique.*

THE DIAGNOSIS AND TREATMENT OF GASTRIC AND DUODENAL ULCERS.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE N. Y. POSTGRADUATE MEDICAL SCHOOL.

THE diagnosis of peptic ulcer is made if we have a distinct hemorrhage from the stomach, which manifests itself by the vomiting of blood or the passing of blood with the stools, and by pains in the gastric region. These are the cardinal symptoms. If, however, the diagnosis of gastric or duodenal ulcer is restricted to only these symptoms, we would fail to recognize a great many cases of ulcer in which these two symptoms have not been noted. We know that we often fail to make the diagnosis of stomach ulcer, because it is found in autopsies that about 4 per cent. of all who die have ulcers in the digestive tract—stomach or duodenum. If we were to restrict the diagnosis to these symptoms, therefore, we would find it in 1 per cent. or less. That is the way we know we do not make the diagnosis frequently enough.

Boas has discovered the fact that there are cases of ulcer in which there is no manifest hemorrhage, but in which the blood becomes recognizable in the gastric contents or in the stools by employing chemical tests, and we call that occult blood. It is not recognizable macroscopically, but we can find that it is there. So he introduced a method of looking for occult blood in the gastric contents or stools, as a help to recognizing this condition. This marked a great advance in the diagnosis of ulcers.

Now, if there is an ulcer in the digestive tract at the cardia, or pylorus, or elsewhere, then at times when there is more activity in the ulcerative process the blood comes out. In a quiescent state there is not enough blood to lead to its discovery in the stools or gastric contents. The ulcer may be there, but you will find no blood, even by these chemical tests, and the reason for that is that the contents of the intestinal tract are considerable, and the blood is mixed up with a great deal of food and water, and part of it is absorbed and digested, so that there is very little left to appear. The consequence is that we can recognize even the occult blood only when there is a considerable amount of it. In the quiescent stage we have ulcers, but we cannot find blood in the gastric contents or stools.

Now we have another test; that is the thread test. Here we have a method by which even when there is no exacerbation of the process, no direct oozing of blood, we can in some instances recognize it any way. The principle of that is that a thread with a tiny bucket attached is left in the digestive tract for quite a period of time—say, given in the evening and left in until 8 o'clock in the morning. As soon as the bucket gets into the duodenum it will proceed as far as the length of the fastened thread will permit it to; it cannot go further and remains there and stretches the thread. If the bucket has remained in the duodenum for two, four, six hours, it has come into direct contact with the walls of the stomach, and if the ulcer is situated at the cardia, lesser curvature, or the pylorus, for instance, the thread has become impregnated with the ulcer surface, which is always moist, and we get a mark on the thread corresponding to the situation of the ulcer. This not only shows the presence of the ulcer, but often the location, for by estimating the distance from the lips to the cardia or the pylorus it is easy to arrive at a fair idea of the position of the ulcer. This test makes it quite possible to recognize ulcers in patients who have no hemorrhages yet, and when there is not yet a distinct oozing of blood—no blood in the gastric contents and none in the stools. It is characteristic for the stain to be quite localized. If you get a sharp stain in a definite spot it is of more value than a stain that is much spread out. That the stain is not caused by an artificial erosion produced by the pulling of the thread, can be shown by the following circumstance: It is not exactly red, but dark brownish; it is not fresh. If you got a stain due to the erosion of the pulling thread it would be a fresh stain of red blood, and it would be more spread out.

How shall we differentiate between gastric and duodenal ulcers?

Years ago it was thought that the differentiation between these two kinds of ulcers was almost impossible. Within recent years the opinion prevails that it is a very easy thing to do, and this is the opinion of Moynihan. In fact, Moynihan says that one needs no tests at all in order to recognize a duodenal ulcer, but that it can be done by the history of the case in association with the clinical symptoms—*i.e.* pain two or three hours after meals; still later, hunger pain—that is, pain allayed by the ingestion of food; the periodic appearance of these symptoms periods of suffering for two or three weeks, interchanging with feelings of euphoria (well-being), chronicity all these years. All these points go, according to Moynihan, to make the diagnosis. He says that nothing else is necessary. If you have these you have a duodenal ulcer.

My opinion is that these points alone cannot be taken for a positive proof of a duodenal ulcer. We may have the above symptom complex and there may be either a gastric ulcer present or perhaps none at all. The fact that such a symptom complex can be caused by gastric ulcer has been demonstrated by patients who have been operated upon. In these the symptoms sometimes were found to be due not to duodenal ulcers, but to ulcers in the stomach situated near the pylorus or along the lesser curvature,

*Address delivered at the meeting of the Canadian Med. Association at St. John, N. B., on July 8, 1914.

even near the cardia. Whether such a symptom complex exists without ulceration I could not say, for I don't have these patients operated on frequently. I could not give the proof, but from what I know I would say that in a great number of cases that have this symptom complex there are no ulcers. But what is of importance is that in these cases where there is so much acidity and discomfort two, three, or four hours after meals, that if that abdominal disturbance continues it will ultimately give rise to ulceration. The ulceration is not the primary factor; it is due to these functional disorders of gastric secretion. If you wait long enough you will have an ulcer.

Now, there is one point more which I wish to speak of; that is that the surgeons nowadays—Moynihan, too—claim that in the symptomatology of ulcer the pains do not appear right after eating, as was formerly supposed, but always two or three hours later. I think that that has been exaggerated, and I must say that the old teaching of our clinicians that ulcer of the stomach is indicated by pain pretty soon after eating is correct. I will explain that divergence of opinion. If there is an ulcer somewhere in the stomach and it is not in the quiescent state, but in an active state we have pain pretty soon after eating is correct. I will explain pain on pressure. The pressure may not be great and still there is pain. But if we have to deal with a latent, quiescent, not active ulcer, at that time we may have no pain. We have a patient, for instance, who has too much acidity—pains two or three hours after meals. The pains are there, no matter whether the ulceration is there or not. In these cases where the great acidity gives rise to an ulcer, the other condition, hyperchlorhydria exists, but the symptoms are not due entirely to the ulceration, but to the primary troubles. The ulcer exaggerates the symptoms. If there is great acidity it makes itself felt sooner. That is the explanation I would give.

An ulcer can, however, exist with a normal acidity and also with a diminished acidity, but in most of these patients there is too much acidity. I have made a chemical analysis before I knew there was an ulcer, and that was found to be an achylia gastrica. The patient had to undergo an operation for gallstones and a gastric ulcer was discovered at the laparotomy.

How shall we make a diagnosis of gastric or duodenal ulcer?

Formerly it was believed that if the pains appeared late after the meals the probability was that the ulcer was in the duodenum. That was taken for a prominent sign twelve or fifteen years ago. Now, as I have told you, Moynihan lays still more stress on that. Another sign is that in gastric ulcer the blood is usually vomited, while in duodenal ulcer there is less vomiting, but the blood appears in the stools, large hemorrhages appearing in the movements and the patient frequently becoming unconscious. But neither of these phenomena is a positive sign in either direction. You may find one or both misleading. Cardiac ulcer sometimes gives rise to melena—blood passing out through the stools —without vomiting. Such instances have been proven by several tests and also by operation. In cirrhosis of the liver, for instance, you find that very often. There are venous ectases, big veins in the esophagus above the cardia, that burst and give rise to hemorrhage—no vomiting—and you may find the blood in the stools. The patient may even die, and you will find at autopsy that there was a bursting of the vessels in the esophagus. These signs are not, therefore, positive enough for duodenal ulcer.

I think the thread test is the best means of recognizing the presence of an ulcer and of ascertaining whether it is in the stomach or in the duodenum.

Not all ulcers can be demonstrated with the thread test, however. For instance, an ulcer on the anterior wall of the stomach will not come in contact with the thread, and there will be no stain on it. Ulcers, however, situated in the cardia, the lesser curvature, pylorus, or especially in the duodenum, can usually be recognized by the thread test. It would be a great exception if there were a duodenal ulcer present and it gave no blood stain on the thread.

If, however, there is a mere infiltration of the mucous membrane, but no raw surface present, or if the ulcer has almost healed, it would give rise to no stain. But in most instances we can recognize ulcer of the duodenum by the thread.

You recognize the position of the ulceration by the distance of the bloodstain from the lips. . . . A bucket which has sojourned in the duodenum shows at the lower part of the thread near the bucket a decided bile stain, and just above is the mark of blood, if the ulcer is in the duodenum. When taking out the bucket you should make a mark on the thread at the lips, and then you can estimate where the stain was made. The distance from the lips to the cardia is 16 inches, and to the pylorus is 22 inches; that is, in medium sized patients; in tall persons it would be somewhat greater; in short persons somewhat less.

If you find when you pull the bucket out that there is no bile stain and that there is no resistance in pulling it out, then the bucket was merely in the stomach, but not in the duodenum. In more than nine cases in ten it will pass if there is no stricture or spasm of the pylorus. If there is a spasm we give the patient atropine and give the thread again and let him sleep with it, and then take it out again. If we find bile at the end it shows that it has been through. X-rays will also occasionally be helpful in establishing a diagnosis of peptic ulcer.

So I have given you these more important points for diagnosis. By employing these means we can discover ulcer more frequently than by any other means we know of.

Now as to treatment, for that is what interests you most. What shall we do with these patients?

You may have cases in which the diagnosis of gastric or duodenal ulcer is made, but the patients do not present many symptoms. They don't suffer much, and they go about their business. They have a little pain and inconvenience, and cannot eat coarse foods, etc. In such cases it may not be necessary to use a very rigorous treatment, for the patient will not follow it. You cannot force him to stay in bed, and he says he has to attend to his business. For such cases we have an ambulatory treatment which can be applied. Of course, it is not so good as the more rigorous treatment, but we can use it in appropriate cases. It consists in first giving the patients large doses of bismuth. That is one of the best remedies in all forms of gastric or duodenal ulcer. Give a large dose of bismuth—say, half a dram three times a day—combined with six or eight grains of calcined magnesia, and then an appropriate diet.

The diet should consist of milk, eggs, cereals, and

a great deal of butter—not too much meat, and no heavy foods; no salads, nothing sharp, nothing peppery, no ice water. That would be the principal treatment in these ambulatory cases. You cannot keep a patient who is going about his business on a restricted diet of milk, or milk and broths, for it would not do. A man at his work must have a more considerable amount of food. You can supplement that diet by telling the patient he should lie down for half an hour after taking the bismuth, and if this does not go he should apply a wet compress over his abdomen at night to act as a kind of sedative; if the pain is very pronounced you may add a small amount of atropine (gr. 1 120) once or twice a day, but that should not be carried out for a long time. Such remedies should be reserved for short periods of time. I saw recently a patient who has been taking atropine for a year, and he has had to increase his dose, and I am not sure that it has not been doing him harm. These strong alkaloids should be used with great care. Atropine has been believed to decrease the acidity, but in this patient there was an acidity of 110; that means more than twice the normal. The prolonged action is injurious. The above treatment covers the mild cases.

We now come to the severe cases. What should be the treatment in those instances where the symptoms are very pronounced and occur principally after hemorrhages? That is the most serious condition in ulcers—large hemorrhages. If the ulcer is accompanied by a considerable hemorrhage, the proper treatment is absolute rest. Put the patient to bed. Don't let him move around much, keep him quiet, put an icebag over the stomach and abdomen and forbid all kinds of food and drink—absolute rest for body and stomach. The medicinal treatment in these cases would be adrenalin—five to ten drops in water, and gelatin, which also acts as a hemostatic. You can give a 10 per cent. solution of gelatin, a tablespoonful three to four times a day; subcutaneous injections of blood serum from man or horse—the latter is the easier to be obtained—are likewise beneficial. Then emetin hydrochloride given subcutaneously once or twice a day, in half grain doses, acts in a similar manner. I have found that very helpful in severe hemorrhages of the stomach and lungs. How it acts, I don't know, but empirically it does act. Then, if the pains are very severe, we should give opiates—a suppository of opium and belladonna.

In such cases you should not bother about the nourishment for the first day or so, for absolute rest is necessary in these cases. Then we institute rectal feeding, and first we have to see that the patient gets enough fluid, especially if he does not get it from the stomach—we all lose a great deal of fluid through expiration, perspiration, etc.—and we do that best by giving a 5 per cent. solution of grape sugar—say, two tablespoonfuls of sugar to a pint of water—and let it run in slowly (Murphy drip)—twice a day. The grape sugar increases the nutritive value of the water; sometimes we give it three times a day. The next day you begin with rectal feeding.

In addition to these water enemas of sugar or salt you try to introduce some additional nourishment. You may give five ounces of milk, a raw egg, and a teaspoonful of sugar with a little salt; beat it up well and inject it through the rectum, giving two or three such injections a day. The rule is that before you give such enemas the bowel should be washed out once daily, but in these cases of ulceration we don't give large enemas. We wash them out with a pint of water and let it come out, and a little later begin with these feeding enemas. That goes on for three or four days. An ulcer cannot heal that quickly. The rectal feeding may be prolonged for a week, but if done longer than that there is too much loss of flesh and the patient becomes exhausted. These feeding enemas are all right, but the nutriment from them is not all utilized, perhaps only about one-third of the amount is taken up by the body; the rest is lost from the system, and that is why in rectal alimentation there is no adequate nourishment possible. It is only a help and we cannot resort to it for a long time. It is only good for short periods of time.

Now what shall we do next? If you are dealing with strong, well-nourished individuals they will stand that treatment for a week or two and lose twenty pounds, and it will not do them any harm, but where you have to deal with thin and weak individuals there is danger of their becoming exhausted and dying, and we must resort to other means. After the rectal alimentation we start them in on the fifth day, say, with small amounts of nourishment by mouth, beginning with strained barley water, milk with barley water—a tablespoonful every hour. The next day, if there is no bad result, give a double amount; the third day give two ounces every hour, and so move up day by day until you reach six ounces. Then increase the intervals to two hours and increase the nourishment—milk, koumiss, barley water, 7 to 8 ounces. Then you begin to add raw eggs beaten up in milk, and run that up to eight eggs every day, and by that time you have reached a date two or three weeks after the hemorrhage, and you can have the patient sit up and give him soft boiled eggs and milk, and increase that diet day by day until you get him stronger and better. When you begin to feed you start in with the bismuth treatment, as in the ambulatory treatment, giving large doses of bismuth.

Now if you have to deal with patients who have run down a great deal or if the rectal feeding is not well borne—many patients have diarrhea—you try first a little opium with the enema, but if this will not go, and they continue to have the diarrhea, what will you do?

In these cases we can start in with duodenal alimentation. We can start even soon after the hemorrhage. I don't like to give it during the hemorrhage, but would not be afraid to use it two days later. In one case at St. Vincent's Hospital, at the request of the attending physician, I instituted it during the hemorrhage. The hemorrhage was so great that the patient almost died, and it could not be checked, and the patient could not stand rectal feeding, so I introduced it at the time of the hemorrhage, and in aspirating I got blood, but I left the tube in, and the patient got well. I recall another patient from whom I aspirated blood, but I simply emptied the syringe and introduced the food a little beyond the place of hemorrhage, and he also got well. Hemorrhage, therefore is not an absolute contraindication to the introduction of the tube, for it cannot do any harm, so far as I can see.

There was a patient in the German Hospital who was operated upon for a plegmon of his arm, and he had a big hemorrhage from the stomach at the same time. That complicated the case. He had a temperature of 103-104°, and he had a septicemia with streptococci in the blood. Dr. Willy Meyer asked if I would risk giving him duodenal feeding, as other-

wise nothing could be done for him. I said I would try, and as soon as the treatment was instituted so that he could be fed he braced up and got well. He had fever for two or three weeks, from the phlegmon and infection, but he got well. I have no doubt that the duodenal feeding saved his life. So hemorrhage is no contraindication to the introduction of the tube. It has to be done carefully. If you aspirate, you must do it slowly.

The principle of duodenal feeding is that the stomach and duodenum are kept at rest, including the ulcer-bearing area, and if you treat them this way you give the ulcer the best chance to heal up. You cannot keep the ulcer free from irritation if there is food in the stomach or duodenum. Say you give the patient milk; the milk causes gastric secretion all the time it is there, and the ulcer comes in contact with this irritating material, and there is no absolute rest possible with any kind of food in the stomach or duodenum. If you wish to carry out the principle of rest you must keep the stomach empty.

As I have said before, we can carry out some—although inadequate—feeding below the affected area with rectal alimentation, but this cannot be employed for two or three weeks, and the duodenal feeding is, therefore, the method of choice. From it we get the best results, for the principle of rest can be absolutely carried out. After the feeding is over you begin to give them liquid food, and then get on to the ordinary diet quite rapidly, except that heavy foods must be avoided.

We have just discussed the dietetic management of very mild and very severe cases of peptic ulcers and it remains, therefore, to detail the treatment of cases of medium severity or the average run of cases. Here the Laube rest cure plays the greatest rôle. Patient is kept abed for about two weeks on a liquid diet. Warm poultices are applied over the stomach during the day, while at night a Priessnitz (wet compress) is employed. I usually give milk, gruels, broths, raw eggs; about seven or eight ounces every two hours; at first four eggs, then eight eggs daily. On the tenth day semi-solid food is added, like farina, soft boiled egg, milk toast. On the fourteenth day some solid food is given—toasted bread with butter, scraped beef, or squab, mashed potatoes; at the same time the patient is allowed to be up half an hour to an hour. From now on the diet is quickly increased in such a manner that within another week patient is allowed to eat most foods, excepting highly seasoned, acid, or too greasy substances.

The Lenhartz diet differs from the one described in that meat and solid foods are given on the third or fourth day of treatment. I personally do not advocate this régime.

With regard to medication subnitrate of bismuth is our mainstay and used as above described. Nitrate of silver may also be tried for a period of two or three weeks, but no longer. It is given in 1 6 to 1 3 grain doses t.i.d., a.c. The patient must be cautioned not to prolong the use of this remedy indefinitely, as argyriasis is apt to develop. In case diarrhea appears the silver treatment must be suspended.

Scarlet red, gr. vii. ss., in wafers may also be employed, t.i.d., p.c., either alone or in conjunction with the other remedies.

Olive oil, one to two tablespoonfuls twice daily, and liquid paraffin, one-half to one tablespoonful twice daily, are likewise beneficial.

The alkalies may be given to combat hyperacidity and atropine to abate hypersecretion. The latter remedy, however, must be used with caution, and not for too long a time, as already stated above.

While the treatment in peptic ulcers generally is a strictly medical one, their sequelæ may require surgical intervention.

The indications for surgical intervention in peptic ulcers may be put as follows:

1. Perforation requires immediate operation.
2. Recurrent profuse hemorrhages (hematemesis or melena or both) endangering the life of the patient require a prophylactic interval-operation.
3. Frequent small hemorrhages, not being influenced by rational treatment, leading to an appreciable degree of constant anemia, demand operative intervention.
4. Cases with constant continuous hypersecretion, accompanied by intercurrent ischochymia, not yielding to treatment, should likewise be operated.
5. Severe pains, not influenced to a considerable extent by a repeated course of rational medical treatment, form a strong indication for operative measures.
6. Strictures of the pylorus leading to ischochymia are greatly benefited by surgical intervention (gastroenterostomy). Beginning benign stenosis of the pylorus can, however, also be treated tentatively by stretching.
7. Ulcer accompanied by tumor-formation and suspected malignancy should likewise be operated.

20 East Sixty-third Street.

X-RAYS AND RADIOACTIVE CHEMICALS IN THE TREATMENT OF GYNECOLOGICAL CONDITIONS.

By EMIL H. GRUBBÉ, B.S., M.D.,

CHICAGO, ILL.

During the past few years the *x*-rays, when used alone or in connection with radioactive chemicals, have produced such striking results in the treatment of gynecological diseases, particularly in fibroid tumors and cancer of the uterus, that medical literature is full of reports lauding this method of treatment. The number of these reports and the large list of cases benefited have established this treatment so well that it bids fair to supplant older and less effective measures.

Undoubtedly this is the most talked of subject in gynecology to-day, and its advent truly marks an era in medicine and surgery in more ways than one. Perhaps the most novel feature of the last Clinical Congress of Surgeons was the fact that two men were asked to come all the way from Germany to tell us how they treat cases of fibroid and cancer of the uterus by nonsurgical methods, *i.e.* *x*-rays and radioactive chemicals. This certainly was a very flattering as well as unique position for a nonsurgical treatment to occupy. Since that time many articles written by surgeons of highest repute have appeared commending in unmeasured terms the efficacy of this treatment. Indeed, results have been so positive that the method has obtained the respect of even the most radical surgeons. It seems that we have reached that stage in the treatment of gynecological cases where conservatism rules, and it is no longer considered an indisputable truth that the only method of treating cancer and fibroid of the uterus is with the knife. All conscientious practitioners know that in cancer of the uterus, at least,

the knife used either as a palliative or as a radical measure has given very poor results. This fact has constantly stimulated the profession to look for something better in other therapeutic fields. To obtain permanent results from their treatment has been their everlasting goal. The world is demanding results instead of palliation.

The treatment of fibroid of the uterus by means of the *x*-ray is not so very new, for, if I remember correctly, it was in the year 1902 that J. D. Gibson of Denver first used this method. The treatment of cancer of the uterus is even older than that. As far back as the year 1899 I treated this condition by means of the *x*-ray and the lead oxide speculum method, and a short time thereafter I used the cavity tube method for the purpose of concentrating the *x*-rays directly upon the uterus through the vaginal canal. In 1902 I read before the American Roentgen Ray Society a paper in which I reported two cases of cancer of the uterus which were cured by the speculum method of *x*-ray treatment. The following year I read before the Chicago Electro-Medical Society a paper in which I reported three cases of cancer of the uterus symptomatically cured by means of the cavity tube method of *x*-ray treatment. In the MEDICAL RECORD, Nov. 1, 1902, in a paper dealing with the *x*-ray treatment of cancer, I said, among other things, that: (1) "The *x*-ray has a pronounced effect upon internal cancers. (2) The *x*-ray has a selective influence upon cells of the body. Abnormal cells are affected more readily than the normal. (3) Hemorrhages and discharges are decidedly lessened and ultimately cease in the majority of cases. (4) Even in the hopeless, inoperable cases the *x*-ray prolongs life, makes the patient comfortable and the last hours free from pain. (5) The use of the *x*-ray is without doubt a highly valuable addition to the therapeutics of malignant disease and cannot demand too much attention from the progressive physician." Let me call your attention to the fact that statements such as the above appear in the present-day literature almost word for word as I made them years ago. It simply shows that now there appears to be an agreement of opinion regarding the properties of the *x*-ray, and what was said about its qualities years ago was not so far fetched after all. Those of us who have been pioneers in the *x*-ray field, those who have lived long enough to find their early statements fully confirmed, are glad to see that clinical experience and testimony from the best professional sources have finally come to our aid and proved that we were right. Our heritage has at last been acquired.

Neither is the use of the combination of *x*-rays and radioactive chemicals as therapeutic agents very new. I think I may claim to have done some pioneer work here, also, for at the International Electrical Congress in 1904 I read a paper entitled, "X-Rays and Radioactive Substances as Therapeutic Agents," in which I reported the results of several cases of cancer of the uterus under this combined treatment. This paper was published in the *Scientific American*. I have made these quotations and referred to this early work of mine in order to fortify the position which I shall take and to show that any opinions I may express further on in this paper have been obtained through extensive experience and mature judgment.

Radium.—This term should not be used, for nobody has any radium nor has any living being ever seen any of it. Radium is an element, and, like many other of the rarer elements, it has not been isolated in sufficient quantities so that we may hold it in the hand and look at it. Whenever radium is mentioned as being sold or used only the compounds of radium are referred to. This fact is not ordinarily known. The most common compounds of radium in use today are the bromide, chloride, sulphate, and carbonate, of which the bromide and chloride appear to be the best for practical therapeutic purposes.

Thorium.—This substance also is used as a compound, instead of in the elementary state. It is radioactive, but in some respects weaker than radium compounds. The most useful combination of thorium is known as mesothorium. For therapeutic use this is just as active as some radium compounds, but its life is only five and a half years, whereas the life of radium compounds is much longer.

Now, what is it in radium compounds, thorium compounds, and the *x*-rays which makes them useful in the treatment of identical diseases? It is the similarity of rays which these three agents give off. These rays have been called alpha, beta, and gamma. The alpha and beta rays do not penetrate the skin and are, therefore, used only for the treatment of superficial lesions. The gamma rays penetrate the densest of bodies, and, because of this property, they are available in the treatment of deep-seated lesions. It is the gamma ray of both the *x*-ray and radioactive chemicals which does the work when these agents are used in the treatment of gynecological diseases. The rays are identical, whether they be obtained from chemicals or from the *x*-ray tube. Right here I should state, however, that only 3 per cent. of the rays given off by the most powerful radium or thorium compounds available today are gamma rays, whereas in the *x*-ray the quantity of gamma rays is practically unlimited. Technically radioactive chemicals are, therefore, only a pocket edition of the *x*-ray. In other words, radioactive substances are very puny therapeutic agents when compared with the *x*-ray and the use of the former is, therefore, much more restricted than is that of the latter.

The radium enthusiasts tell us that they can make radiographs (shadow pictures, the same as *x*-ray pictures) through the thin parts, like the hand of the human body, with radium compounds after an exposure of from several hours' to two days' time. They consider this a remarkable phenomenon. Well, with the *x*-ray we have almost unlimited power in this direction, for we can make pictures *instantaneously* of not only the thinnest parts of the human body, but of the thickest parts as well. Photographically, then, the *x*-ray accomplishes in a second of time what radioactive chemicals can do only after many hours of exposure. Again, those who work with only radioactive materials tell us of the, to them, great ionizing property of these chemicals. They state that an electroscope can be discharged if the radioactive substance is brought in close proximity to, or made to touch, the instrument. It appears that these so-called investigators do not know that the power of ionizing the air, and, therefore, the ability to discharge an electroscope, which the *x*-ray possesses is so great that you don't have to come near or touch the instrument with the *x*-ray tube in order to discharge it; that these effects are so powerful and penetrating that we can send them through the human body, a stone or brick wall, and a hundred feet of space, and still show this ionizing

property to be of higher degree than that which is obtainable from the most concentrated radioactive materials in use today. Further argument need hardly be necessary to convince one of the relative position which these two measures should occupy in therapeutics. My own opinion, expressed several years ago, which has been borne out by others and by my own later experiences, is that radium and thorium compounds are adjuncts to the *x*-ray, but not necessary adjuncts, and I believe we could very well get along without them. All who have used and studied first hand the combined treatment have come to the conclusion finally that the *x*-ray is the superior remedy, and my prediction is that when the limitations of radioactive chemical treatment become more generally known and the enthusiasm which comes with all new things, especially when they are sensationally advertised in the newspapers, has subsided, that then the *x*-ray will be used alone rather than combined with radioactive substances in the treatment of gynecological cases. It seems to me that we do not need expensive radium or thorium compounds as much as we need to study and develop *x*-ray therapy. Remember, when I make these statements I am not biased in my opinions concerning the relative merits of these two therapeutic measures, for I have used and still use both.

The gynecological conditions which have been most favorably influenced by radiotherapy (I use the term in its broad sense, gamma ray therapy probably would be a better one) are cancer and fibroid of the uterus and ovaries. The variety of fibroid tumor which is most readily affected is the interstitial kind. At present it is questionable if the other kinds, *i.e.* pedicled, subserous, and submucous, are not best treated with the knife. Those patients over forty years of age who are just approaching the menopause age or who have passed it are most suitable for this treatment. In younger women the method is successful, but the results are not so pronounced nor as readily brought about as in older patients. This treatment is also indicated in those cases of fibroid in young women in which anemia, goiter, or heart disease preclude the possibility of performing a successful surgical operation with the knife. In cases which might be suitable for surgical treatment, but where the patient absolutely refuses the aid of the knife, and in those cases which are so far advanced that the knife offers no hope of eradicating the disease, if the *x*-ray does not cure the case it will always offer relief and is the best palliative we have today. The treatment is also of great service as a postoperative measure to prevent the recurrence of a malignant growth. Other menstrual disorders, especially menorrrhagia, yield to this treatment. It can be used to control the amount of blood and the duration of the period. For climacteric hemorrhage this treatment is particularly useful. It may also be used to produce an artificial menopause, *i.e.* sterility in young women in whom pregnancy is contraindicated.

The question of the effectiveness of this treatment for cancer has been very emphatically settled by several investigators, notably Ashoff, Gauss, and Krönig. More than two years ago in several cases in which exploratory laparotomy was performed on cases of undoubted cancer which had been subjected to massive doses of *x*-rays, they found upon making histological sections of the tissues so treated, not only decided degeneration of the cancer cells, rendering them incapable of further growth, but that these cells ultimately became actually replaced by connective tissue cells. We know now how radiotherapy cures these cases. All who attended the last Surgical Congress and saw Gauss' histological sections of specimens showing progressive changes in tumors must admit that this was one of the most emphatic demonstrations of the therapeutic qualities of an agent that has ever been brought to the attention of the medical world. It is, therefore, not necessary for me to emphasize the importance of these experiments and histological tests. They speak for themselves and must be of the greatest possible significance in convincing the medical profession of the soundness of radiotherapy in the treatment of the diseases mentioned.

It has been known and scientifically proven over and over again that the ovaries are very sensitive to the cumulative effects of *x*-rays. The function of these organs can be decidedly altered by exposure to the rays. As the exposures are continued, a progressive atrophy ensues, accompanied by destruction of the ova. This property of the ray suggested their use for the purpose of inducing the menopause artificially. Undoubtedly the *x*-ray has here a very useful field.

As to the technique for applying radiotherapy in these conditions, considerable difference of opinion exists among operators. Successful results have been produced with quite a variation in technique. However, if treatments are to be given from the outside, through the abdominal wall, all operators agree that the three factors to pay most attention to are: (1) That there must be a high enough vacuum in the *x*-ray tube to allow us to send the rays into the lesion; (2) that the vacuum be kept stable throughout the treatment; (3) that large quantities of electric current be passed through the tube. A high vacuum tube generates penetrating rays. Such rays are absolutely essential in order that the therapeutic qualities of the *x*-ray may reach the pathological tissue. The exact vacuum to be used in a given case depends largely upon the thickness of the flesh wall through which the rays are to be passed, the presence or absence of large quantities of fat, and the size and thickness of the tumor. In a general way, however, it may be said that very high vacuua are needed for all cases.

A very important condition necessary to success with this method is the keeping of the vacuum stable throughout the entire treatment. This can be accomplished by the use of a definite amount of electrical energy delivered to the tube at a constant voltage, a Bauer qualimeter, and heat dissipating media at the anode of the tube. Water-cooled or air-cooled *x*-ray tubes must, therefore, be used in this work. I have recently designed a tube in which the anode is kept cool by a constant stream of compressed air which is delivered at a pressure of from thirty to fifty pounds to the back of the heated surface of the anode. By means of a chimney arrangement the heat is driven away from the heated parts.

To prevent sparking of the patient due to condenser effects and also puncturing of the tube from the same cause the patient and apparatus must be grounded. In order to prevent as much as possible the local destructive effects upon the patient's skin, those rays which produce damage, *i.e.* alpha and beta rays—must be filtered out. This is done by interposing between the tube and the patient's body one or more sheets of aluminum having a thickness of from 1/16 to 1/8 of an inch. To aid in the concentration of the rays the tissues near the tube may be compressed by means of the compression cylin-

ders commonly used in radiography. This brings the active rays nearer the pathological tissue, and, therefore, causes them to act more energetically than would otherwise be the case. Compression of the skin is also utilized to squeeze the blood out of that portion of the tissues in direct line with the ray. This has been found to be an aid in preventing dermatitis. In addition, compression tends to keep the tube distance constant. All who have made radiographs know that a picture made with a small diaphragm is sharper than one made with a wide opening or none at all. The principle upon which the diaphragm works is that of concentration of *x*-rays. This same principle is available whenever we make use of the *x*-ray therapeutically.

My own technique is to divide the lower abdominal region into a few fields, usually from 4 to 8, each of which is exposed separately to the *x*-ray. Depending upon the size and location of the lesion, the external abdominal wall is divided into the areas to which and through which the *x*-rays will pass into the diseased parts. Each area is exposed from 5 to 10 minutes. Thus in a given case, depending upon the number of separate areas, the length of time for treating each area, and the time consumed in changing the apparatus about, a single treatment may consume from 30 to 120 minutes.

For the purpose of painless compression and definite localization of the rays I use what I call a deep tissue treatment localizer of my own design. This instrument consists of two $\frac{1}{8}$-inch thick plates of aluminum $8\frac{1}{2}$ and $9\frac{1}{2}$ inches in diameter, respectively. Between these aluminum plates is placed a combination metallic plate which I shall term the middle plate. It is so fixed that it revolves around a central axis which is fastened to the aluminum plates. One-sixth of the area of the middle plate is cut out, and through this opening the *x*-rays are allowed to reach the tissues which are to be treated. The middle plate protects all parts which are not to be exposed. By revolving the middle plate different sector portions of a circle are opened up to the *x*-rays, and thus in six separate exposures I can treat an area included in the size of the entire circle. By compressing and treating only a small field at a time, heroic doses of the rays may be given without much detriment to the skin. The patient receives the treatment while lying on the back. The localizer is placed upon the naked body and with the aid of a compression cylinder having a diameter of 7 inches the instrument is kept in a permanent position throughout the whole treatment.

It is asserted that the greatest number of deep penetrating or gamma rays are generated at the time when the *x*-ray tube first lights up. Therefore, a device for interrupting the electric current rhythmically is utilized by some operators. My own opinion is that the idea of the use of a "rhythmeur," as it is called, is a theoretic point which has very little bearing upon the ultimate effects of the treatment. Patients have been cured without the rhythmic interruptions of the circuit. I admit, though, that rhythmic interruption of the circuit has some effect in keeping the anode of the tube from getting too hot and thereby preventing the lowering of its vacuum.

In measuring the dosage of the *x*-ray, the most practical values are obtained by using from 3 to 5 milliampères of current for from 5 to 10 minutes for each field, the tube being at the proper distance from the surface of the body. When such large quantities of *x*-rays are given it is desirable to wait an appreciable length of time before giving another treatment so that cumulative effects may be studied. Fifteen days are usually allowed to intervene between treatments. As a rule, a series of treatments is necessary to produce symptomatic cures.

I am of the opinion that when this treatment is used to produce sterilization or artificial menopause, smaller doses of the ray should be used than in the treatment of fibroids or cancer. I have observed that diarrhea, fatigue, pains in the breasts, as well as in the region of the ovaries, are common while the patient is treated with heroic doses of the ray, while under smaller doses the cessation of the function of the ovaries is so gradually brought about that no disagreeable by-effects are produced. The best time to give the first sitting in menorrhagia, or fibroid, is immediately after a menstrual period. Menstruation usually is increased after the first two or three sittings; thereafter there is a gradual decrease, until it finally ceases entirely. Complete amenorrhea can usually be produced in from four to six months. All the symptoms which usually accompany a normal menopause follow the *x*-ray produced menopause, *i.e.* flashes of heat, headache, digestive disturbances, and general nervousness. In cases of fibroid, as a rule, the uterus becomes perceptibly smaller after the first two or three sittings. In cancer the effects of the treatment are seen in the rapid disappearance of the clinical symptoms of the disease. There is cessation of hemorrhage, suppuration, and foul-smelling discharges; the tumor becomes smaller and the patient gains strength and weight. I believe that symptomatic cures can be produced in all cases of cancer of the uterus if the treatment is begun before glandular involvement is present. In this connection it should be stated that when there is glandular involvement the affected glands should also receive *x*-ray treatment simultaneously with the tumor.

When the *x*-ray treatment is combined with radioactive chemicals, the latter is simply placed as near the cancerous growth as possible and left *in situ* from one hour to several days, the time depending upon the chemicals' strength and the nature of the pathological condition. I have found glass tubes shaped to fit the uterine cavity most suitable for holding the chemicals. These tubes can be kept in place by means of tampons.

I would not have the reader understand that the other older methods for administering *x*-rays are not now used. They are, especially the cavity *x*-ray tube method which allows us to treat such conditions as epithelioma of the vagina and uterus, more directly than the external method which I have described at length. More recently several European operators have introduced a combination of both the external and the cavity tube methods. Drs. Bumm and Wernekros use three *x*-ray tubes simultaneously in treating fibroid and cancer of the uterus. One tube introduced into the vagina is a cavity tube, the active part of which touches the uterus, while two ordinary tubes attached to compression cylinders are applied to the external abdominal wall either both in front or one in front and the other at the back. By means of a special mechanism all three tubes are excited by the same electric generator. This would appear to be rather a heroic manner of applying the rays, but then most of the patients who come for treatment need heroic therapeutic measures if we are to help them at all. Undoubtedly, rapid cumulative effects are necessary in these cases and such effects should be

produced in the shortest possible time consistent with safety.

The question of both *x*-ray and radioactive chemical treatment producing or increasing metastases has come up very frequently. If metastases occur in a given case I believe that they were present when the patient came for the first treatment, but were not discovered, or they have been produced by giving too small doses of *x*-rays or radioactive chemicals which instead of stopping the spread of the disease stimulated the cancer cells to greater activity and therefore caused the disease to spread. The ordinary weak applications—sample treatments I call them—which are most commonly given are not only worthless but are positively dangerous. Therefore inefficient dosage of *x*-rays or radioactive chemicals may be a cause of metastases.

The splendid results obtained with this treatment, especially in fibroid and cancer, place it far beyond other gynecological procedures. It has become so well known as an effective remedy in these conditions that some very able surgeons have practically adopted it as routine treatment. Drs. Bumm and Wernekros say it is a remedy which acts almost with the certainty of a specific and marks a new era in gynecological practice. Dr. Krönig, himself a surgeon and an authority on gynecological operative work, says that he has abandoned the use of the knife in these cases. Dr. Doderlein says that it is the treatment of choice, and, since its beneficial effects cannot be doubted, resort to other measures is unnecessary. He also reminds us that because of its painlessness, economy, and comparative safety, patients will welcome it when they will refuse other treatment.

Up to the present time medical literature records over 2,000 gynecological cases as favorably influenced by the radiotherapeutic method. Hundreds of operators are now at work treating cases and within a year or two reports will be forthcoming from these investigators. Then a much larger field can be surveyed and so the exact position of this treatment will be ascertained.

130 North State Street.

TREATMENT OF THE TOXEMIA OF PREGNANCY BY THE DUODENAL ENEMA.

By ELLICE McDONALD, M.D.,

NEW YORK.

Toxemia of pregnancy, on account of its unknown etiology, has been variously and ineffectually treated. The most popular theory as yet advanced has been that it is a phenomenon of antiphylaxis. This theory, however, has a number of opponents who maintain that the cause of toxemia of pregnancy is essentially intestinal absorption. Undoubtedly, from a practical point of view, this is true. When the intestinal elimination is improved the toxemia of pregnancy gets better, but unfortunately the revolt of the stomach and the constant vomiting makes it difficult to apply any medication to the intestines to cleanse them and promote excretion.

Toxemia of pregnancy has been variously described as reflex, neurotic, toxic, and other. These subdivisions are purely academic and serve no useful purpose. All forms of vomiting in pregnancy are toxic, although in the beginning there is undoubtedly some reflex stimulus. As reflex vomiting often occurs from other causes, such as eye strain, psychic shock, etc., so it is not unreasonable to suppose that it is the reflex element in the early part of pregnancy which causes some of the morning illness and vomiting. However, in the toxic conditions this is not a very great factor. The practical direct treatment is the elimination by means of the intestines and the addition of water to the blood and tissue. There is apparently in most toxic vomiting a dehydration of the body tissues. There is often probably kidney irritation and occasional hemolytic phenomena.

During the last 18 months I have treated twelve cases of toxic vomiting of pregnancy by means of a duodenal tube, which is a modification of the Jutte tube. The procedure is as follows: A small rubber tube about the caliber of 12 F, is thrust into the stomach after the pharynx has been anesthetized by a local anesthetic spray. Most patients are able to swallow the tube themselves after the first treatment, but at the first attempt, in order to maintain the patient's confidence, it is better to cocainize the throat and insert the tube with the patient sitting up in a chair. The tongue is depressed with the forefinger while the tube is thrust down with the other hand, the patient being advised to breathe deeply and slowly, in order to prevent any nausea. When the tube is down about 22 inches, 8 ounces of a solution of sodium chloride in amount a trifle stronger than the physiological solution, is injected by means of a syringe through the tube into the stomach. This usually effectually neutralizes the tendency to vomit. The tube is then thrust further down to about the length of 28 inches. The patient is then placed upon her right side in a semiprone position. The waist bands should be loosened. After a few minutes, suction is made by means of a vacuum bottle and syringe to withdraw some of the contents through the tube. When bile or intestinal juice is obtained, it is considered that the tip of the tube has passed the duodenum. It is needless to say that the stomach should be empty for several hours before the treatment is done. It is usually possible to pass the pylorus within five to seven minutes.

An injection is then made by means of a gravity can of a liter of a solution containing from four to six grams, by measure, of granulatar sodium sulphite. This solution has the effect of precipitating itself through the intestines; within thirty minutes from the time the last of the sulphate solution is introduced into the tube the first of it appears at the anus.

This "duodenal enema" does not cause pain or straining, and it does not irritate the anus as do saline cathartics. It washes everything before it and the resulting stool is highly colored with bile and has the raw smell of the juices of the small intestines. Any small solid particles such as the particles of orange taken immediately before the beginning of the treatment, may usually be recognized in the resulting stool. Any other salts than the sodium sulphate, such as magnesium sulphate, common salt, sodium carbonate, may be used, but I have found sodium sulphate the most efficient and effective in the toxic conditions. It may be possible that the high sodium content of the blood is responsible for this action. The purgative effect of the salt is not obtained. Apparently all that is necessary is that the solution used should be hypertonic to the blood. Sodium sulphate will not cause sulphur poisoning as will magnesium sulphate. If it is absorbed at all, the sodium molecule is taken and the sulphur molecule rejected, while, with the magnesium sulphate, the sulphur molecule is absorbed and the magnesium molecule rejected.

This treatment has had the most extraordinary effect on all the cases of toxemia of pregnancy which I have been able to treat. No patient has required more than a single treatment, as after the first general hygienic measures can be instituted, such as regulation of the bowels, drinking a large quantity of water, and a simple diet. Amongst the twelve cases no patient, save one, has had any vomiting after the treatment. In the beginning several patients had a number of treatments because I did not believe it possible that one treatment would cure them.

One patient in particular had a most severe attack of toxic vomiting and she was brought to me by her physician and carried into my office. Had I known that she was so ill I should not have requested that she be brought to me; I should have gone to her. She had vomited incessantly for six weeks. The odor of acetone on her breath was noticeable on entering the room. Her face was furrowed with dark rings around her eyes. The treatment was given with little difficulty and the duodenal enema passed through the gut to the anus within twenty minutes after the last of the sulphate disappeared, washing out her intestines completely. The odor of acetone immediately vanished from her breath and the dark circles under her eyes disappeared as though they had been washed off with a wet cloth. She returned to her home, ate her supper, and did not vomit thereafter.

This extraordinary result in toxemia of pregnancy encouraged me to try the treatment in other cases of toxemia and I have had uniformly good results. I have also used this method in a number of other toxic conditions with good results. It is useful in acute toxemias, diabetes, liver disturbances of various kinds, and other toxic conditions. It is possible, by means of reduction of the salt content below the tonicity of the blood, (for example, less than that of physiological saline), to pass all the solution through the kidneys instead of through the intestines. The first urine comes straw colored and very soon the urine is as clear as crystal. For this reason, this method is also useful in kidney conditions and I have treated two cases of pyelitis of pregnancy by this method with gratifying result. In both there was a considerable degree of toxemia. One patient had a temperature of 104° and pulse 120 and was rapidly going down hill. The temperature fell to normal the day following the treatment and did not rise thereafter, although the treatments were given on several succeeding days.

The results depend somewhat upon the skill of the physician. The duodenal tube should be of a very good quality of rubber, which is difficuut to obtain in this country. I have my tubes made in Paris with an apical as well as a lateral aperture and of the caliber of 12, 13, and 14 F. The tube is, as I have already stated, a modification of the Jutte tube. The only contraindication to the treatment is an acute or subacute abdominal intlammation. In fact, it is a good test of chronic appendicitis for any such chronic inflammation usually shows marked tenderness in the right iliac region during the treatment.

The results of this treatment in toxemia of pregnancy makes me believe that it is probable that the chief factor in the toxemia of pregnancy is intestinal stasis and intestinal absorption, whatever may be the direct cause of this. It seems possible that the chief locality of this absorption is in the upper part of the small intestine, more particularly in the duodenum; and in spite of the vast number of theories as to the etiology of toxemia of pregnancy, I would suggest another—that this poisoning may be due to absorption of the duodenal toxin, which also causes a poisoning in intestinal obstruction. This duodenal toxin has been shown by the experimental work of Maury Draper and Hartwell, who found that the duodenum actually secreted a poison which was responsible for a great deal of intoxication in intestinal obstruction. Hartwell recognizes as well that there was a condition of marked dehydration which was responsible for a great deal of the intoxication. It is possible that this duodenal toxin is one of the etiological elements in the toxemia of pregnancy. Certainly if the duodenum and upper intestines are cleared out, the toxemia seems to be immediately relieved.

Incidentally, the study of the intestinal action in these cases and in others that I have treated by this method makes me believe that in intestinal stasis the real factor at fault is the musculature and muscle tone of the intestines themselves and the lack of syphonage action of the stool passing the anus. I do not believe that kinks, membranes, or flexures have anything to do with intestinal stasis, or contribute, save in exceptional cases, to the causation of this condition. Lane's kink, Jackson's membrane, etc., are too commonly found at operations in cases that have not been troubled with constipation, to believe that they enter into the etiology of intestinal stasis to any degree whatever. The treatment above described will obviate any necessity for operations for intestinal stasis, inasmuch as most operations are ineffectual at the best. It should also be recognized that most cases of intestinal stasis are associated with a lack of development in other parts, such as gastroenteroptosis, etc., and that this quite frequently is only a part of the symptom complex of what my teacher Noble called "congenital hypoplasia," and, while it may be possible to operate upon the intestines, it is impossible to make bodies over and give new nervous systems. However, the simplicity of this treatment and the ease with which it can be applied by the patient herself give a reasonable hope of benefit in these cases of intestinal toxemia. Experiments in regard to intestinal disinfection by means of the introduction of various germicides have been undertaken by this method.

This method of treatment of the toxemia of pregnancy gives a reasonable hope of its cure in the early stages. The simplicity and ease of the treatment make it possible that it should be given with little if any discomfort. Its benefits are far reaching and may throw some light upon the etiology of the disease.

174 West Fifty-eighth Street.

THE VALUE OF EUGENICS IN HUNTINGTON'S CHOREA.*

By C. R. McKINNISS, M.D.,

Norristown, Penn.

Chief Physician, Dept. for Men, State Hospital for the Insane, S. E. District of Pennsylvania.

This disease has received considerable attention in Europe and this country under the names of Huntington's chorea, hereditary chorea, family chorea, adult chorea, and others, though if we may judge by the cases reported it is more prevalent in Amer-

*Read before the Psychiatric Society, Philadelphia.

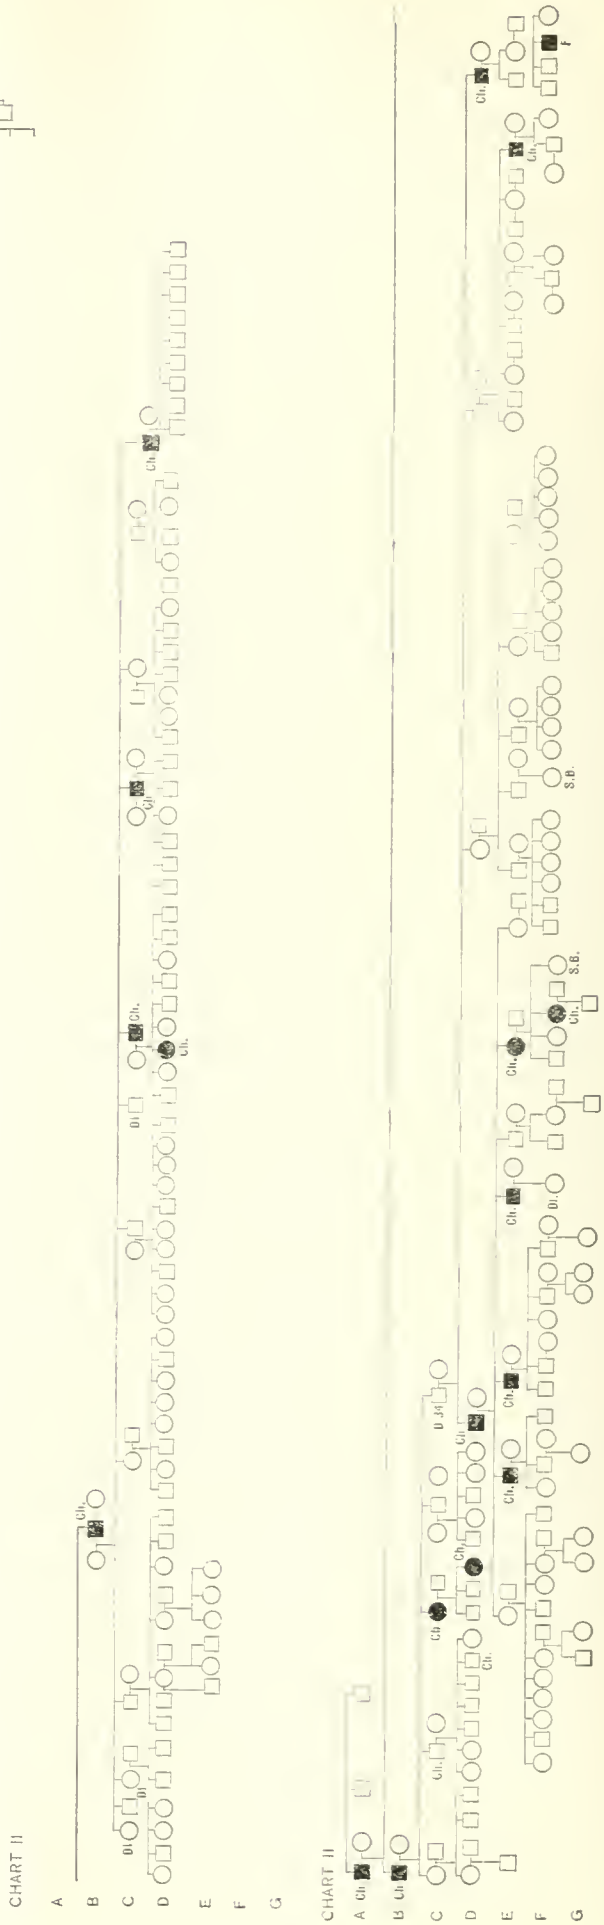
ica. Many cases find their way into hospitals for the insane due to the mental deterioration, which almost invariably accompanies the disease, but that it is far from being a common disease is indicated by a recent statement of Starr that he has never seen a case.

The earliest description we could find of this disease in America was in 1841, when C. O. Waters wrote of it as observed in south eastern New York, where it had the laity name of "megrums" or "megrim." He called attention to the marked heredity and said it was more common in the lower classes of society. He never knew a case of it to occur in a patient, one or both of whose ancestors were not, within the third generation at farthest, the subjects of this distressing malady.

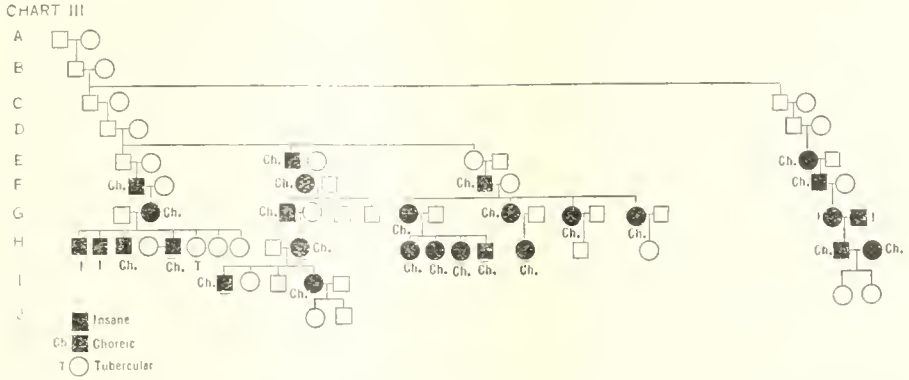
In 1863, Lyon, while house physician at Bellevue Hospital, New York, called attention to the disease and said that he had been familiar with it since childhood. He stated that the belief in the transmission of the disease from parent to child was so strong that marriage into these choreic families was forbidden under penalties of disinheritance and social ostricism. He also mentioned a tradition which ascribes the ultimate origin of the disease to a visitation upon those who reviled and mimicked our Saviour while undergoing crucifixion—that they and their children were ever after affected with choreal irregularities.

About 1872 Huntington described the disease as observed by himself, his father, and grandfather, who were practising physicians in the eastern part of Long Island. He used the name hereditary chorea and protested against calling it Huntington's chorea, but the name is still frequently used. He referred to the disease as occurring "almost exclusively on the east end of Long Island and that it obeys certain fixed laws." He found it more common among men than women and emphasized three characteristics: (1) The hereditary nature; (2) A tendency to insanity and suicide; (3) Its manifesting itself as a grave disease only in adult life. Of its hereditary nature he says: "When either one or both the parents have shown manifestations of the disease, and more especially when these manifestations have been of a serious nature, one or more of the offspring almost invariably suffer from the disease if they live to adult age, but if by chance these children go through life without it, the thread is broken and the grandchildren and greatgrandchildren of the original shakers may rest assured that they are free from the disease. This you will perceive differs from the general laws of so-called hereditary diseases, as for instance in phthisis or syphilis, when one generation may enjoy entire immunity from their dread ravages and yet in another you find them cropping out in all their hideousness; unstable and whimsical as the disease may be in other respects, in this it is firm, it never skips a generation to again manifest itself in another, once having yielded its claims it never regains them."

The study of the disease since Huntington wrote this description of it has confirmed his statement almost entirely and possibly added a few additional facts, which we shall try to bring out by reports



of some choreic families which we have had the opportunity to observe and by the aid of a few charts which we have prepared. We shall not take up the clinical picture of the disease, as it is more or less familiar to us all, and the pathology will



also be passed over as the findings, so far, have hardly been sufficient to explain the disease. We do wish to mention, however, a theory advanced by Dana, that the disease is a late development of a teratological defect, the brain being abnormal and the cells having the capacity to live only thirty or forty years. He compared it to hereditary ataxia, where there is a defective vitality of the sensory neurons of the spinal cord and after a period of years the decay begins. Gowers (1903) favored a similar belief, describing the condition as an abiotrophy.

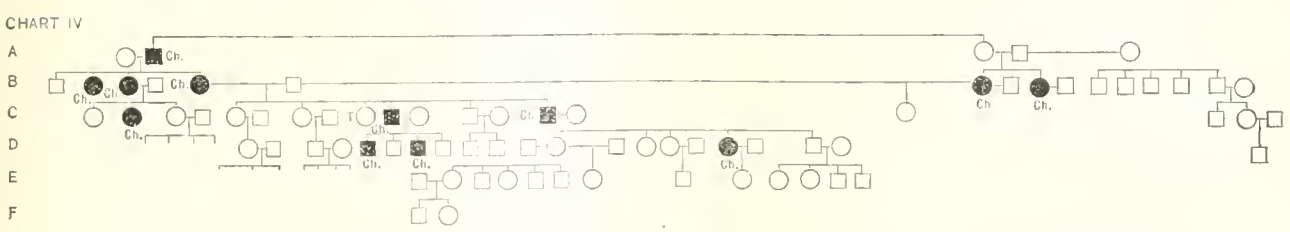
It has been said that the disease manifests itself earlier in females and that they are less frequently affected than males, and our experience has agreed with this. It is also said that the disease is more frequently transmitted through the female members, but this was not the case in the families we have observed.

I wish to emphazie the point that more knowledge of the disease may be obtained by exhaustive study of each separate family than by the grouping of several families for compiling tables. Menzies has made a study of two choreic families, and of twenty-five choreic members in one family he found the average age at onset to be 27.6 years and the age at death 43.7 years, while in the second family the average age at onset was 37.2 years and age at death 54 years; so we see there may be wide variation.

It is comparatively easy to trace the genealogy of a family which has such conspicuous landmarks to guide us and only occasionally have we seen attempts to conceal the facts. Most of the chronic families can be traced back to New York State, especially Long Island, or to the southern part of the New England States, though the original source of entrance to America is not known. In fact, we know of its presence in Germany, England, and Scotland and possibly other countries, so that it is not a disease of one nation.

It is not necessarily a disease of low mentality, and the members of some of our families have held positions of trust and respect, not to be obtained without some intellectual attainments.

CHART I.—(Littler, Bloomer, Allen family.) This represents one branch of a family of South Central Ohio, three members of which we have had the privilege to examine. We were able to obtain a history of thirty-three members. In the first generation, A 1, the only member we could trace was a choreic woman; she had three daughters, all of whom were choreic. B 1, 3, and 4; one of these, B 1, married and had seven children, five sons and two daughters. C 1 was a patient in a hospital for the insane. In his case the tremor began at 32 years of age and a few months after he came near drowning, having been carried down in a swift stream and lodging in some drift where he was rescued and resuscitated with difficulty. He died in the institution of bronchopneumonia at 42 years of age. C 2, his wife, was not choreic and came from apparently normal stock. None of her people were subject to nervous or mental diseases. Their two children, D 1 and 2, are nervous and especially so when ill, but have not yet reached the age of development of chorea. C 3 was also examined by me and later became a patient in a hospital for the insane. The onset in this case was at 40 years of age following an injury. One month before the tremors began the vehicle in which he was riding was struck by a trolley car and he was thrown to the street, receiving injuries which confined him to bed in a hospital for six weeks. I might say that there was no question of damages against the trolley company in this case. This man married a woman of normal stock and they have seven children, ranging in age from 11 years to 27 years, who so far are apparently normal. C 5, female, was choreic, had one child who has not been traced. C 7, female, was not choreic and died of tuberculosis, had one child apparently normal at 8 years of age. C 9, male, choreic and a patient in a hospital for the insane, has several children who have not been traced. C 11, male, not choreic at 50 years of age, and has a normal family of seven children. C 13, male, not choreic, died at 20 years of age of



typhoid fever. In this family the disease has been transmitted only through females. All of the second generation were choreic, and of the seven in the third generation, who have reached the age at which the chorea might be expected to develop, only one has escaped.

CHART II.—(Benedict, Longshore, Rose family.) Three brothers, A 1, 3, and 4, came from England to Connecticut some time prior to 1750. One moved to Pennsylvania and two to Ohio. The descendants of one brother, A 1, have been traced through seven generations and over 500 descendants have been recorded. The ancestor of this branch of the family moved to North Central Ohio about 1810 and was so choreic that he was believed to have been possessed by the devil. Of his twelve children, only two developed chorea and the disease has appeared only in these two branches of the families. On this account the other branches are not represented on the chart. Seventeen members have been choreic, twelve men and five women. From the chart it would appear that the disease skipped one generation to appear again, as C 10 did not have chorea, but at 34 years of age the man died of typhoid fever. Had he lived the disease may have become manifest. Three members have been patients in hospitals for the insane and other members are residents of Ohio, North Dakota, Iowa, Missouri and California.

CHART III.—(Park, Peck, Bliss, Andrews, Williams family.) This chart has been worked out from H 5, a male choreic patient in a State Hospital for the Insane, and except for that immediate branch of the family, I am much indebted to the Eugenics Record Office at Cold Spring Harbor, Long Island, whose field worker, Dr. Muncey, has done such excellent work in the study of this disease. A 1 was born in England in 1608 and came to New England about 1638, being one of the founders of the colony, and most of the descendants have resided in Connecticut. This family, whose members have shown more than average mental capacity, have produced a physician, H 5, who was a choreic; the onset being at 40 years, the course progressive with mental symptoms. Death occurred at 65 years of age, from arterio-capillary fibrosis. F 7 was the town clerk for 15 years and was a member of both branches of the State Legislature, but he died choreic and insane. H 19 is a mental scientist. H 18 was an educator, author, and editor; educated at Columbia University and later a professor in that institution, but was choreic and insane and a suicide. Of the forty-seven members traced, twenty-four were found choreic, ten males and fourteen females; the transmission has been about equal between two sexes. All the descendants of G 7 and 8 were choreic and are now dead. G 2, F 12 and 13 were sexually immoral. It will be noticed that G 12 and 13 were insane, though we do not know if they were choreic, but following the law of the disease one of them at least must have been choreic. Their son, H 18, was choreic and his wife, H 19, was choreic. She was a descendant of William Peck, a brother of A 1. They had two children, one of which died from an overdose of paregoric; the other, a nervous, though intelligent girl of 19 years, whose future, shadowed by a duplex inheritance, I am sure none of us will envy. There are now members of this family in Connecticut, Pennsylvania, Illinois and France.

CHART IV.—(Ricker, Schewell, Dingler, Miller family.) This family has been traced from C 14, who was our patient for seven years, dying at 66 years of age of arteriosclerosis. The onset of the tremor was at 40 years of age shortly after he had fractured both legs. Before coming to us he had killed his wife and attempted suicide. Our chart shows descent from a brother and sister, A 2 and 3, by the name of Schewell. From the brother fifty-one descendants have been traced, ten being choreic and equally divided between the sexes. From the sister, A 3, there came only three descendants, two being choreic and are now dead, the other died in infancy, so that this branch of the family is extinct. The disease has been transmitted about equally by the males and females. Four members died of tuberculosis, which is hardly a sufficient number in a family of this size to indicate a tuberculous tendency. It will be noticed that B 6, the father of our patient, married twice, his wives being first cousins and both choreic, though he came from normal stock, having six normal brothers and sisters. The immediate descendants of A 2 were a son who could not be traced and three daughters who were choreic. An interesting part of this chart is A 3 and her descendants. She was not choreic and marrying a normal man had two daughters, both of whom were choreic. Her husband, A 4, married the second time and had a line of normal descendants, except for two tuberculous. A 3, however, died at 40 years of age of cerebral apoplexy and we know that arteriosclerosis is also a somewhat characteristic finding in Huntington's chorea. The determiner must have been transmitted from A 3, as her two daughters developed chorea. Now the question will arise, did this woman transmit the disease to her offspring without herself being affected or would she have developed chorea later in life if she had escaped the apoplexy? Knowing Huntington's chorea to be an essentially dominant disease, I think we are justified in the belief that had she lived the chorea would have developed.

Is our present knowledge of this disease sufficient to formulate any laws of heredity, and from the standpoint of eugenics what should be our attitude?

1. It has been generally proven that to have Huntington's chorea, one or both of the parents if they live to past middle life must have been choreic. There has been one or two cases reported where this was not found, but it has also been said that these exceptions might bear closer investigation.

2. There is no positive law of anticipation in Huntington's chorea. We can not say positively what the result will be if a person takes a choreic mate. Nor in early life of the individual can we say chorea will or will not develop. In Chart I the second generation, consisting of three females, were all choreic and in the next generation of the same family there were seven born, five of whom lived to adult life and four of these were choreic. Some of the other families show an equally positive result. We have not seen a single case in which a choreic parent raised a family to adult life but what one or more of the children became choreic. You might say, "Yes, but if once it skips a generation the disease will not again manifest itself in that branch of the family," but who can say when or where it will skip.

3. Certainly in a disease whose transmission from parent to child is so marked as we find in Huntington's chorea, we can not emphasize the danger too much, and should advise always against marriage of these individuals.

A BRIEF OUTLINE OF THE CARBON DIOXIDE BATH AND ITS USES.*

By ALBERT WARREN FERRIS, A.M., M.D.,

SARATOGA SPRINGS, N. Y.

SUPERINTENDING DIRECTOR FOR THE COMMISSIONERS OF THE STATE RESERVATION.

HYDROPATHY, or water cure, practised by empirics and charlatans, deservedly fell into disrepute and is near extinction. Even its name is etymologically incorrect. Hydrotherapy, the science of the use of water as a remedial agent, ranks today as a subdivision of therapeutics, equal in importance with electrical treatment or the administration of drugs. Yet it has never had the attention paid it which it merits, in spite of repeated examples of brilliant results published for generations in medical and lay periodicals, and in spite of emphatic statements by eminent teachers and clinicians, who have mastered its technique and applied its principles with physiological sagacity. Medical colleges, always slow to increase their administrative expenses by extending their curricula, have with great reluctance considered the creation of chairs of hydrotherapy. Dispensaries and clinics, in a very few cases, grudgingly establish hydrotherapeutic departments and then suffer them to languish, in some instances, because of insufficient consideration by the physicians serving in general medicine departments, and because of the peculiar defensive and offensive attitude toward any new suggestions which characterizes many institutional physicians and nurses.

Ernst Brand, of Stettin, Germany, published in 1861 the method he had devised of treating typhoid fever with baths of cold water at exactly prescribed temperatures, at regular intervals and for definite periods, and accompanied by friction. He claimed and proved that his method resulted in a great reduction in the mortality from this dread disease. Liebermeister, Jürgensen, Ziemssen and other established authorities approved, advocated and practised his method. Yet over twenty years of argument and objection followed, and the greatest reluctance was exhibited in many countries to the abandonment of the drug or "expectant" treatments of typhoid, with their customary mortality of 22 to 32 per cent., and the substitution of the Brand bath method, with its mortality of 3 to 8 per cent. To this day there are scores of unconvinced physicians of limited education, and hundreds of lay pundits, who are simply bursting with pseudo-medicine, learned from the man in the street and from the newspaper paragraph, who advise or insist that "other means" be tried first, while the recoverable typhoid sufferer is drifting and sinking into the tenacious clutches of death. Who can calculate how many hundreds of thousands of valuable lives, sure to have been lost under the drug or "expectant" treatment of typhoid, have been saved by the use of the Brand bath? And yet, it is opposed today in certain quarters.

What wonder, then, that the medical apostles of general hydrotherapy have been forced by want of interest, ridicule, or absolute hostility, to fight every inch of the way to recognition and ordinarily decent professional consideration?

Our own Baruch, the most eminent exponent of hydrotherapy in America, sadly disturbed the equanimity of several eminent delegates to a congress of physicians at London, England, in 1913, by advocating a certain form of hydrotherapy in insomnia. He was informed that drugs only were being considered in the discussion of hypnotics. While advocating the use of an American nostrum, they were unwilling to discuss a very natural and successful measure of demonstrated usefulness in securing sleep.

Dr. A. Vogl, medical director of the Bavarian army, wrote as long ago as 1896, "The insufficient education of medical men in physical therapeutics, especially in hydrotherapy, is a serious defect, which injures physicians in their earlier practice, and for which it is difficult to compensate later." He adds: "Hydrotherapy should be taught in its entirety, as Winternitz has done, upon a physiological basis. By lectures and clinical demonstrations it should be brought before the student just as other therapeutic agents and methods are offered to him as obligatory branches of study. When this is done, hydrotherapy will become the property of all physicians, and not be practised as a special and distinct method."

Germany was aroused and took an advanced position, years ago, in the teaching and practice of hydrotherapy, but America is still lagging behind. In spite of the teaching and example of Baruch, the American master; in spite of Jacobi, Brayton Ball, William H. Draper, James, H. P. Loomis, Peterson, and Gilman Thompson of New York, and Meigs, Wilson, Tyson, and Musser of Philadelphia, it must be said that the profession of neither city takes a real interest in hydrotherapy. It is but sporadically used and but superficially grasped, as even certain well-known textbooks bear witness; for in them the explanation of the procedures and their rationale are very meagre, and the suggested methods of prescribing are almost always so incomplete and ineffective as to suggest helpless ignorance of the practice of this very valuable form of treatment.

Hence poor people or those of limited means do not get hydrotherapeutic treatment in our cities, and the greater number of well-to-do patients are sent out of town to sanitariums or to foreign health resorts, where full equipment and skillful treatment are well nigh assured.

A well-known college clinic in New York has allowed its hydrotherapeutic equipment to be abandoned, interest in hydrotherapy having so far failed of realization that neither the general faculty nor the chiefs of other departments of the clinic have sufficient regard for it, and also young medical graduates who will interest themselves sufficiently to maintain the department, as assistant physicians, being apparently unobtainable.

It is amazing that very many physicians have never paid any attention to hydrotherapy and have not a single work on the subject in their libraries. Such physicians, naturally, when interrogated by patients or others, find it safer and easier to conceal their ignorance by deriding the practice, and thus the great public is denied information regarding a most valuable form of treatment. Yet a superficial acquaintance with the physiologic basis of hydrotherapy is easily obtained. Everyone realizes the peripheral stimulation that follows hot or cold baths, but few appreciate the fact that powerful hygienic, dietetic and therapeutic factors are thus available. Systematic repetition of stimulation or depression through the peripheral nerves results in a permanent condition, following tem-

*Read at the April meeting of the Saratoga County Medical Society.

porary reaction. Following the nerve stimulation, secondary effects in vascular territories occur through conveyed impulses, modifying function according to the change in the supply of nutritive material.

Among the most important thermic and mechanical effects of hydrotherapy are the vascular contractions and dilatations secured, and also the changes in the vigor and frequency of the heart's contraction, through the transmission of neural impulses to the muscular tissues, cardiac and vascular. Changes in the blood pressure; alteration in the constitution of the blood (leucocytosis as well as an increase in erythrocytes following the application of cold, with a moderate reduction in erythrocytes following heat, in general); increase in the normal metabolic activity; change in the functions of excretion and secretion, as clearly observed in the case of skin, kidneys, alimentary tract and glandular apparatus; all these are effected by proper hydrotherapeutic procedures when fresh, or sweet, water is employed.

Mineral Baths.—We turn now, in this rapid survey, to mineral baths, by which term we mean baths whose water contains a large proportion of solid or gaseous substances in solution. These substances excite a form of cutaneous reaction which differs from that noted in the baths prepared with fresh water. Water is absorbed, as in all baths at moderate temperatures, as shown in an increase of weight, but none of the dissolved solid constituents of the mineral water is absorbed, as demonstrated by the experiments of Winternitz and of Rohrig, Lehmann, Thompson, Rabateau and others. The gases permeate the skin, however, exerting an irritation upon the peripheral nerves, whence the distinctive chemical stimulation. This stimulation causes a dilatation of the peripheral capillaries, and an impression, through reflex influence, on the centers regulating the heart action as well as the nervous system, whereby increased oxidation results and metabolism is augmented. Osmosis to a varying extent is very probable, since, during a bath, the skin separates two saline fluids of different specific gravity, the blood and the mineral water. If no actual diffusion takes place, at least the blood and the intercellular fluid proceed toward the surface of the body, producing a peripheral hyperemia.

The carbonic dioxide bath is variously termed "acid," "effervescing" or "carbonated," and these names are properly used when the waters employed are highly charged with CO_2, and contain varying and even negligible quantities of solids, always excepting the special CO_2 baths used in the Nauheim system for treatment of certain heart conditions. In these, irritation of the skin by brine produces a slight initial hyperemia.

The results of the CO_2 baths are due to the following agencies: (1) The temperature of the bath; (2) the CO_2; (3) the radioactivity of the water; (4) the presence of special chemical irritants such as the calcium chloride and magnesium chloride in the Nauheim bath system.

The gas stimulates the skin, causing a rosy tint as it clings in minute bubbles to the entire submerged body surface. "The irritating effect upon the sensory centripetal nerves, as well as upon the heat nerves, is manifested in a sense of marked prickling, as well as a sense of intense heat, particularly in the genital region," says Kisch. "With the redness of the skin is associated contraction of the unstriated muscular fibers, which is especially marked in the scrotum and in the nipples. The tactile sensibility of the skin is materially increased. The stimulating effect of the carbon dioxide upon the sensory cutaneous nerves extends to the nerve-centers, and, through radiation and reflex action, through the entire nervous system; and thus induces a feeling of general well-being as well as an increase in all the nutritive processes."

The action of the CO_2 bath on the heart and vascular system is of prime importance. There have been wild enthusiasts who claim impossible results, as well as prejudiced pessimists, who shut their eyes to all testimony and refuse to believe the truth. Over 75 years of observation and study have resulted in the elaboration of a system of tremendous value in cardiovascular diseases, when carefully prescribed, properly applied and constantly supervised by a competent physician. The testimony of the orthodiagram is conclusive. The subjective symptoms of the patient three months or more after the termination of the CO_2 bath treatment are proof enough for the practitioner.

In the treatment of incipient arteriosclerosis, the CO_2 bath is employed with success. In many cases with marked sclerotic changes and a high blood pressure, the treatment has reestablished the circulatory equilibrium, relieved an engorged liver or congested kidneys, and reestablished in these organs a relatively normal circulation. In an engorged liver the poison generated during inactivity of the hepatic cells does the most harm. The CO_2 bath increases the capacity of the cutaneous vessels, and obstruction is removed from the internal organs through the distribution of a quantity of blood, thus lessening the demands made on the cardiac muscle.

In many forms of kidney disease the carbonic oxide bath is of service as adapted to the individual case, assisted by strict diet, proper exercise and out-of-door life.

Chronic muscular rheumatism, lumbago, and many forms of neuritis, are markedly and rapidly benefited. In addition to the carbonated baths, fomentations and douches of mineral water, with massage, are often of avail in obstinate cases. Articular rheumatism is most favorably influenced by the CO_2 baths, and the heart is protected from damage by very early treatment instituted shortly after the termination of the acute stage. Late cases of articular rheumatism, even of chronic character from the start, are ameliorated by the CO_2 baths. In many cases, pain, stiffness, and disability disappear without any other treatment.

In connection with dietetic control, as also passive and active exercises, CO_2 baths are beneficial in arthritis, the nutritional disturbance of joint cartilage. Probably a large measure of the success of the Saratoga bathing waters in joint affections is due to their radioactivity.

Obesity should receive such treatment as the condition of the heart, kidneys and joints indicates. Special diets should be prescribed according to the condition present, and reduction is secured by means of various water, electric, and other heat treatments. Suitable exercises, used passively and actively, following a course of close study of each case. In many instances, difficult breathing, swelling of the extremities, weak heart action, constipation, stiffness in the joints, etc., disappear as the treatment advances. In many cases dullness, apathy and irritability are removed very early.

Carbonic oxide baths are very useful in restoring poise, removing nervousness and irritability, and alleviating insomnia, as well as in building up tissue in the victims of neurasthenia, or "nerve fag."

In cases of chronic alcoholic or drug addiction, the CO_2 baths constitute a very important part of the rapid withdrawal method and in the constant care through which new tone and vigor are obtained. The skin is influenced to greater activity and general nutrition improves rapidly with the baths as adjuncts to the ordinary treatment.

Exhaustion, following acute disease or surgical operation is an indication for the employment of careful, graduated CO_2 baths.

Elimination is secured by placing the patient in a bath at 98°, and heating it up gradually, while he is in the tub, to 110° or less, or to 112°, if reduction is the object. Following withdrawal from the tub, a spray at 105° to 85° will check the perspiration, or a hot pack will encourage it if desired. It is followed usually by out-door exercise. The duration of the tub bath should be from ten to twelve minutes.

The sedative, or calmative, bath should be administered at the temperature of 98° to 100° and continue for eight or ten minutes, though some patients should not be subjected to over 95° of the CO_2 bath. A spray at the temperature of the bath and then cooled rapidly to 85° should follow emergence from the tub.

For a tonic effect the bath is administered at 75° to 85° for two to five minutes, with friction.

Radioactivity.—The split products of radium, resulting from its decomposition, are called the alpha, beta and gamma rays. The alpha rays are atoms of helium in very rapid motion. After these atoms are separated, or projected, the residual radium is in gaseous form and is termed radium emanation, or niton. During the change into niton, beta rays are evolved. These resemble negative electricity and are the chief therapeutically active rays. They have the same penetrative power as the Roentgen rays, and resemble the cathode rays projected within the Roentgen tube. The gamma rays penetrate to a great depth, and are also of therapeutic value, but are less understood than the beta rays.

Radioactivity is efficacious in inflammatory conditions, gout, rheumatism, myalgias, neuralgias, sciatica, etc., apparently because of its power to cause decomposition of uric acid compounds and other products of defective or perverted metabolism, and perhaps because of its effecting increased activity of enzymes and ferments, and because of its bactericidal properties.

Some mineral waters are radioactive for a very brief period, because they contain merely radium emanations, while others are active for a very long time because they contain dissolved radium salts. All of the twelve Saratoga waters tested showed radioactivity. Of this feature the following statement is made, concerning five of these waters, by Messrs. Moore and Whittemore, of the Bureau of Mines of the U. S. Department of Agriculture: "The very large proportion of the radioactivity due to dissolved radium salts is quite exceptional, and * * * it is reasonable to suppose that this statement applies to those not examined for dissolved radium salts."

The residues, sediments, or material deposited by the water about the outlets of eight of the springs, are also radioactive, which fact is further evidence of the presence of radium salts.

Under State supervision, CO_2 baths are now administered in two bathhouses with limited facilities, now existent in Saratoga Springs. Fuller opportunity for proper and most comfortable administration of the CO_2 bath in all varieties, and with skill and exactness, will soon exist for the physicians of the State and of large parts of the country, when the State of New York develops its great plan for the erection of a complete Spa and health resort at Saratoga Springs, comprising the building of bath houses and a central drink hall, instituting schools for the training of attendants in hydrotherapy and massage, and enhancing the present conditions and environment of the village, in order that the visiting patient may find rest, peace, diversion, "the soft influences of Nature," and skillful medical care and direction, conscientiously and scientifically provided.

GENERAL DIAGNOSIS AND TREATMENT OF DISEASES OF THE PANCREAS.

By I. W. HELD, M.D.,

NEW YORK.

ATTENDING PHYSICIAN AND RADIOLOGIST TO THE HAR MORIAH HOSPITAL.

It is due to the progress made in surgery on the one hand and in physiological chemistry on the other that we owe our advancement in the diagnosis and treatment of diseases of the pancreas. We need only compare the splendid monograph of Oser in 1898 with the newest compiled works of Albu, Frank, Müller and others to appreciate what has been accomplished in that direction. The foundation to the studies of the diseases of the pancreas was laid by the classical experimental work of Pawlow in 1898.

In order to arrive at a diagnosis it is essential to study the patient from the standpoint of the functional derangement of the pancreas and the subjective complaints. In the former we demonstrate by laboratory methods the degree of disturbed physiological function of the pancreas either in its internal or external secretory property; in the latter we study the symptom complex the patient presents. In order to understand the pathological significance of the pancreas it is essential to review briefly the physiological function of pancreatic secretions.

The pancreatic juice is best obtained either by injecting secretin into the blood or by a permanent or temporary fistula as advised by Pawlow and Heidenhain. The pancreas has in most cases two ducts, an upper one that opens along with the bile duct, and an opening lower down. In the dog the lower duct is larger; in man and in the cat the upper one is larger. To establish a pancreatic fistula we cut out a small piece of the duodenal wall and make it so that the papillæ of the lower duct should open in the middle of the mucous surface. The integrity of the gut is restored by suturing in a single line of stitches the margins of the wound in the duodenum, and the excised piece is brought to the surface and stitched in the middle of the abdominal wall so that the greater part of the pancreatic secretion will escape by the fistula, and be collected by the insertion of a cannula into the duct, or by attaching a glass funnel below its orifice. Care must be taken not to allow any of the juice to come in contact with the abdominal wall, because of its proteolytic property. In order that the con-

tinuous flow of pancreatic juice should not seriously affect the animal's health, milk must be given to the animal freely with the addition of sodium bicarbonate, in order to replace the loss of that salt. On a fasting stomach there is no flow. One to one and one-half minutes after food is given the flow begins, and it is at its maximum when the food passes from the stomach to the duodenum, ending after two and one-half to three hours. Four-tenths per cent. hydrochloric acid increases the secretion of pancreatic juice; carbohydrates likewise increase secretions; oils also stimulate the secretion but not to the same degree as the acids and carbohydrates; proteids have but little effect, and alkalies have none. Weak acids affect the flow of pancreatic juice only when directly introduced into the duodenum, or into the upper loop of the small intestines. This latter action is undoubtedly caused by a hormone in the small intestines, called secretin. In order to produce secretin the mucous membrane of the small intestine is ground up with 4 10 per cent. HCl, neutralized while boiling by the continuous addition of drops of NaOH. The coagulable proteins are precipitated, and the filtered solution contains the secretin. This solution is only stable in an acid medium. In the process of digestion the following takes place: The acid chyme enters the first portion of the duodenum, and a certain amount of secretin is produced at once. The secretin is carried by the blood stream to the cells of the pancreas exciting secretions of the alkaline pancreatic juice. As soon as sufficient juice has been secreted to neutralize the acid chyme, the formation of secretin and the further production of pancreatic juice cease. The amount of pancreatic juice secreted during digestion depends on the quality and quantity of the food taken, and the time it remains in the stomach.

The alkalinity of the pancreatic juice corresponds to n 10 to n 7 sodium bicarbonate, or it is as alkaline as the gastric juice is acid. It contains a nucleoprotein which diminishes as secretion proceeds, and becomes richer in alkalies. The most important constituents of the juice are the ferments or their precursors.

The ferments of the pancreatic juice are trypsin, steapsin and amylopsin. The proteolytic property of trypsin is brought about by what is known as enterokinase in the succus entericus and it has a greater action on the proteins than the pepsin, namely, it splits the proteins into aminoacids. Only a small part of the proteins is not attacked. Trypsin acts not only in an alkaline medium, but also in a slightly acid and acts best in a neutral medium. The neutralization is brought about by the acid secretion of the stomach coming in contact with the alkaline secretion of the duodenum during the process of digestion. Pancreatic juice causes milk to clot; this is probably not due to a rennin in the pancreatic juice, but is the first stage of proteolysis. The second ferment of the pancreatic juice is amylopsin, which acts on the starch molecule, converting it into dextrose and glucose.

The fat-splitting ferment of the pancreatic juice, steapsin, is active in an alkaline, neutral, and slightly acid solution. The steapsin breaks up the fats into palmitic, stearic, oleic acids, and glycerine. In an alkaline medium the fatty acid unites with the alkali to form soap. Lipolysis is four to five times stronger when bile is added. The above described secretion of the pancreas is known as external secretion.

Besides the external secretion of the pancreas the important quality of internal secretion comes into consideration. By means of the latter, the carbohydrate metabolism, the burning of the sugar, the relation of the secretory function of the pancreas with that of the thyroid and chromaffin system, and by a neurochemical property (Ehrmann, Albu, and Bickel) influencing the metabolism of proteids and fats, are brought about. It is the credit of v. Mehring and Minkowsky to have demonstrated the importance of the internal secretion of the pancreas and to have shown that removal of the pancreas causes fatal diabetes. Sandmeyer demonstrated that a partial extirpation of the pancreas causes curable diabetes, but if the organ continues to undergo degenerative changes diabetes progresses and death results. Minkowsky demonstrated that in a depancreatized dog, even part of the protein is converted into sugar. Embden and Salomon even showed that the end products of the proteins, the amino-acids, glycocol, alanin, and tyrosin increase the sugar contents in the animal. Of the fats it is the glycerine that adds to the sugar formation in pancreatic diabetes (von Norden). All carbohydrates certainly increase the sugar formation with the exception of levulose, part of which is deposited as glycogen in the liver and the muscles. In pancreatic diabetes the external temperature has a decided influence on the formation of sugar, cold increases, warmth diminishes, sugar formation. Minkowsky and v. Mehring explain the occurrence of diabetes by the loss of the external secretion of the pancreas, failing to regulate the sugar metabolism. They proved that when a piece of pancreas was transplanted into a depancreatized dog diabetes was prevented. According to many authors the lesion is in the islands of Langerhans; this is, however, not a settled question yet. Many authors observed diabetes in sclerosis, atrophy, or fatty degeneration of the island of Langerhans. others again found the islands extensively diseased without any diabetes. The process of glycolysis by the pancreas is still in dark. Albu maintains that the process exists in the parenchyma of the cells. Lépine explains that glycolysis is brought about by the blood carried to the lymph and thence to the pancreas, especially to the islands of Langerhans. This acts on the preferment, which according to O. Cohnheim is a hormone in the muscles causing glycolysis. Be this as it may, so much is certain, that the internal secretion of the pancreas has a decided influence on carbohydrate metabolism. The result of the relation of th eother organs of internal secretion to that of the pancreas has been utilized to demonstrate a loss of function of the pancreas, and hence this must be touched upon briefly. Loewi showed that adrenalin which stimulates the sympathetic system causes mydriasis in animals without a pancreas, while in those with a pancreas, where the antagonistic action of the pancreas on the suprarenal body is present, no mydriasis occurs. The cases cited by Glässner and Schwartz, as well as the fact that in human beings with diabetes a 1:1000 adrenalin solution 1 drop into the eye causes mydriasis, demonstrate the relation of the pancreas to the suprarenal body. The relation of the internal secretion of the thyroid to that of the pancreas is shown by the frequensy of alimentary glycosuria and the not infrequent occurrence of fatty diarrheal stools in Graves' disease.

From what has been said above it would seem very probable that derangement in the physiology

of the pancreas would manifest itself so easily and be readily demonstrated by the disturbed action of the ferments and the deranged carbohydrate metabolism. This can however only be done in a certain number of cases by the methods to be described below. In a number of other cases the pancreas may be quite diseased and all our functional tests should still be negative. This is to be explained as follows: (1) The pancreas has two ducts and in case of a closure of one the second one is still allowing the secretion to escape and be active. (2) Even if both are occluded the erepsin of the small intestine discovered by O. Cohnheim acts on the proteids, the bile on the fats, the ptyalin on the starches, and the bacterial action on digestion replaces the digestive functions of the pancreas. For the erepsin to be active it is essential that the gastric secretion should be perfect. (3) As long as a small part of the pancreas is not diseased it is liable to assume the function of the entire pancreas. (4) It is not improbable that there is at times accessory pancreatic gland in the upper part of the small intestine. (5) On this I lay particular stress, the negligence to carry out the laboratory tests early in pancreatic disease before compensatory action has had time to take place. I am certain that just as soon as we shall learn to look for pancreatic disease by all known methods as well as we do to-day for gastrointestinal diseases, diagnosis of disease of the pancreas will become the rule and not the exception.

Diagnostic methods demonstrating the efficiency of the external secretion of the pancreas.

The original assertions of Brugsch, Hesse, Rosenberg, and others that in disease of the pancreas the N. loss is increased from the normal 7-8 per cent. to 20 per cent. has not been confirmed by other observers. It is different, however, with the finding of muscle fibers in the stool (creatorrhea). In severe cases muscle fibers are found macroscopically, in milder cases only by the aid of the microscope. In order to facilitate the finding of muscle fibers in the stool, Albu and Adolf Schmidt have devised a special meal for that purpose. The former uses one-quarter of a pound of broiled or boiled calf's thymus and examines the stools for muscle fibers, the latter gives one-quarter of a pound of lean, slightly broiled steak and follows this with a capsule of charcoal in order to recognize the stool. It is essential in case we find muscle fibers to rule out achylia gastrica, increased peristalsis of the small intestines as a result of catarrh, or the excessive intake of meat, and the fact that some people will not fully digest slightly broiled meats. Sahli gives a gelatodurat capsule hardened with formalin and filled with iodoform, salicylic acid 0.15, or methylene blue 0.02, and looks for the respective chemicals in the sputum and urine in four, six, to eight hours. He bases his test on the principle that such a capsule is only acted upon by the pancreatic juice. The investigations of all other observers on the subject agree that the test is unreliable. A modification of the Sahli capsule was suggested by Müller and Schlecht. They base their idea on the fact demonstrated by Ury, that the stool contains an active ferment, Müller and Schlecht therefore place the formerly hardened gelatodurat capsule filled with charcoal in a stool of the patient who received a laxative the night before. The stool with the capsule is placed in an incubator at a temperature of 100° F. and examined from between two to twenty-four hours. If after twenty-four hours the capsule is not opened, they conclude that trypsin is absent. The method of Müller and Schlecht with the serum plates is too complicated for practical purposes, and hence omitted here.

More important and readily carried out, therefore applied in most clinics, is the O. Gross casein method. It is based on the fact, that the digestive products of casein brought about by trypsin are not coagulated any more by dilute acetic acid. The method to be described also serves for the quantitative determination of trypsin. Method: 5 grams of feces are thoroughly rubbed up and treated with 45 c.c. of 1 per cent. sodium carbonate sol., and rendered neutral with sodium bicarbonate. Now the feces sol., is filtered until all clear. 1:1000 neutral casein sol. which is prepared as follows: 1 gram casein is dissolved with 1 10n NaOH, and to make it neutral 1 10n HCl is slowly added and now filled with distilled water up to one liter. In order to prevent decomposition of the casein sol., a few drops of toluol are added. Test: To each of 8 test tubes are placed 10 c.c. of the neutral casein solution. Now we place in the first tube 1 c.c. of the feces, in tube 2, 0.5, in the third tube 0.2, and the fourth tube receives 0.1. The rest is again diluted with distilled water in the dilution of 1:10 and the other four tubes receive now as much of the newly diluted solution as the first four tubes did of the first solution of the feces. The tubes are now placed in an incubator at a temperature of 100° F. for 24 hours. After that time we test the tubes for cloudiness with a 1 per cent. acetic acid sol. In the presence of trypsin the tubes remain clear on the addition of the 1 per cent. acetic acid solution, if trypsin is diminished the acetic acid solution causes cloudiness only in the first tubes, and when absent it renders all the tubes cloudy. The stool to be examined is to be obtained after a laxative.

The method of Volhard is intended to demonstrate trypsin in the stomach contents. The patient is given 200 c.c. of olive oil or 250 c.c. of sweet cream. This breakfast is preceded one-half an hour before by 0.5 gram of calcined magnesia, and 0.5 gram of the same powder one-half an hour after breakfast. The stomach contents are aspirated 45 minutes after, and allowed to stand. The lower layer is examined for trypsin. The best method is the one of Abderhalden and Schittenhelm, known as the silk peptone test. One-half gram of 0.5 peptone is dissolved in 1 c.c. of the gastric juice to be examined. A mildly concentrated sodium bicarbonate solution is added to render the contents weakly alkaline. Some of the gastric contents are boiled to destroy the trypsin, to which 0.5 peptone is added. Both tubes are placed in the incubator at a temperature of 100° F. and examined 24 hours later. If much trypsin is present there are enough tyrosin crystals found to be visible to the naked eye, if trypsin is diminished tyrosin is found microscopically, and if trypsin is absent tyrosin is not found at all. The method is a very useful one and is recognized by such authorities as H. Strauss, Ehrmann, Albu, Frank, Hemmeter, Friedenwald, and others. This method is, however, also not fully conclusive because regurgitated erepsin into the stomach is liable to produce tryosin crystals, and, as shown by Michailow, gastric diseases, like pyloric stenosis, cancer of the stomach, and even the swallowed mucous of the pharynx rich in leucocytes is liable to interfere with the test.

Adolf Schmidt uses the nuclein test with the idea that nuclein is only digested by the nuclease of the

pancreas (Iwanoff). For the test small pieces of meat hardened in alcohol and colored with hemotoxylin and placed in gauze bags are given to the patient and the stools examined for nuclei. If nuclei are found in excess, the pancreatic function is considered deficient. Brugsch has lately modified the test by giving a thymus capsule stained with iron hemotoxylin and hardened in lycopodium.

The test for trypsin by the Mett's albumin tubes is undoubtedly very valuable and recently pointed out by Lifschutz of Charkow to be the most reliable. It may be used either in the stomach contents after a Volhard oil breakfast or in a specimen of feces obtained after the laxative. The test is carried out in the same manner as it is done for the determination of the presence of pepsin with the exception that pepsin is determined in an acid medium and for trypsin we must examine in an alkaline medium.

Disturbance of the Digestion of Fat.—The occurrence of fatty stools in diseases of the pancreas has long been recognized. It must not be forgotten, however, that closure of the choledochus by stones, inflammation, or tumor of the gall bladder, disease of the small intestines, increased peristalsis of the gastrointestinal tract may give rise to fatty stools. We should only attach importance to the finding of fat in the stools when there is an associated creatorrhea, also when jaundice is accompanied by stasis in the gall bladder, and tumor, cholecystitis, or growth of the gall bladder can be ruled out. The staining of the stool with sudan III brings out the fatty crystals and fatty needles more clearly even when small quantities of fat are present. Heating converts the needles and crystals into droplets of fat. If there is excessive fat in the stool, the characteristic clay color results. The stool should not be mistaken for the acholic stool which can be avoided by shaking the stool with ether, and the known bichloride test. In very severe cases the excessive fat in the stools makes the same look buttery. Albu and Ehrmann have lately pointed out that when a pancreatic preparation is given to a patient who has fatty stools as a result of a disease of the pancreas, the fat in the stool diminishes but the muscle fibre is uninfluenced. The tests to demonstrate fat disturbance are those of Winternitz and Ehrmann. Winternitz bases his test on the fact that the ethylester of the higher fatty acids depends chiefly on the steapsin in the pancreas, the bile alone is not able to change the ethylester. He uses 3 to 4 c.c. monoiodbehen ethylester with milk; after 3-5-10 hours he examines the urine and saliva for iodine. If iodine is set free he concludes that the pancreas functionates normally. Ehrmann gives the patient 30 grams of rice with 75 grams palmin and ¼ liter warm water and some salt. Two to two and a half hours after the meal is taken the stomach is emptied by the stomach tube. The fatty contents of the stomach are determined by the following solution: Petroleum ether 90.0 c.c.; benzole ad. 100.0 c.c.; 10 c.c. of the filtered stomach contents are shaken with 10 c.c. of the solution; then the fatty part is treated with 3 per cent. cupric acid solution. The fatty part colors emerald-green and the intensity of the color indicates the quantity of fat present.

Disturbance of the Digestion of Carbohydrate in Diseases of the Pancreas.—To determine the disturbance of diastase the method of Wohlgemut is used. To 5 grams of rubbed up feces is added 20 c.c. of 1 per cent. NaCl solution. We use eight test tubes, into each of them 5 c.c. of 1 per cent. starch solution is placed. Now we add to each tube the same quantity of the feces solution, as it is done in the determination of trypsin. The tubes are placed into an incubator at a temperature of 100° F. After 24 hours we test the sol. with a drop of a 1:10 lugol solution. If the starch is not completely digested, we get a blue color; where erythrodextrin is present the color is red.

The newest and the one that seems to be most promising method to obtain directly pancreatic juice is the duodenal tube devised by M. H. Gross of New York, Hemmeter of Baltimore, Einhorn of New York, and lately modified by Palefski of New York. The method is simple and especially with the Gross tube most easily accomplished, and it is to be hoped that in the near future it will be as frequently used for the diagnoses of pancreatic diseases, as the stomach tube is to-day for gastric diseases. There are already important publications by the above named authors, and by Crohn of the Mount Sinai Hospital of New York.

Disturbances of the Internal Secretion of the Pancreas.—Knowing from physiology the relation of the pancreas to carbohydrate metabolism, we should never neglect to examine the urine for sugar, acetone, and diacetic acid. In cases where sugar is not found in the urine and we still have reason to suspect a disturbance in the pancreas we should test the tolerance of the patient for sugar by giving him 100-150 grams of sugar and see whether alimentary glycosuria is produced. Adrenalin mydriasis as a diagnostic means was already mentioned. The Cammidge test is complicated and not conclusive and has practically been given up.

All the methods outlined above have their shortcomings because the digestive action of the pancreas can be carried out by the smallest healthy portion of pancreas left, the ptyalin, the gastric juice, the erepsin, and the bacterial action, but it is still our duty to carefully examine by all recognized methods for pancreatic deficiency if we expect to make the desired progress in the functional diagnosis of diseases of the pancreas.

Symptomatic Diagnosis.—It will not be possible for me to give a detailed description of all the diseases of the pancreas. An attempt will be made to give a short description of the symptoms characteristic to all the diseases of the pancreas with a brief outline of the symptoms present of the special diseases of the pancreas; the former will come under the heading of general symptomatology, and the latter under special diagnosis.

General Symptomatology.—The general symptoms are those of digestive disturbances and are not characteristic. Only a limited number of symptoms may lead one to suspect a disease of the pancreas. Such are: pressure and pain in the epigastrium with a repugnance to meat. Vomiting is likewise a frequent symptom upon which some authors lay particular stress. Pancreatic juice has been observed in the vomitus by some. The constant presence of bile in the vomitus is a characteristic feature, provided biliary diseases and regurgitation through the pylorus can be ruled out. Ptyalism is considered by some a pathognomonic symptom, because there is a relation between the pancreas and the salivary glands, the latter assuming vicarious function in pancreatic disease. Pain in the epigastric region is not diagnostic. The kind of pain, however, namely, its sudden onset, its extraordinary severity, and the inability to touch the part during the attack may awaken suspicion. The seat of the

pain is almost always around the umbilicus and radiates to the left hypochondrium. The light clay colored voluminous stools containing fat and muscle fiber are very suggestive.

Objective Symptoms.—In most cases there is a marked loss of weight. This is so important that we should carefully inquire as to whether our patient lost weight, because the disease affects mostly obese people, and, therefore, a considerable loss of weight may not be obvious. Of course, there are exceptions to the rule and a case of advanced sarcoma of the pancreas is reported in literature where the patient had lost no weight. Icterus is a symptom that must be dealt with in detail, because it occurs in other diseases as well. In pancreatic diseases it comes on either suddenly or gradually, and is the result of pressure on the ductus choledicus by an inflamed head of the pancreas or a tumor. In stones and inflamed pancreas icterus is intermittent; in tumor it is persistent and progressive. Icterus plus stasis in the gall bladder which on palpation corresponds to a hydrops of the gall bladder should lead us to suspect a disease in the pancreas. In two cases that I had occasion to observe at the Har Moriah Hospital the icterus and large gall bladder were very marked. Of course we should carefully rule out a tumor of the gall bladder itself, or stones lodged in the gall bladder and also in the common duct, the former giving rise to a large palpable gall bladder, and the latter to jaundice. Hepatitis with inflammation of the biliary passages must likewise be excluded. The Mayos, Kehr, Borchard, and others have demonstrated lately that not only in diseases of the biliary passages is the pancreas often found secondarily diseased, but in diseases also of the liver, especially in atrophic and hypertrophic cirrhosis. It is interesting to note that observers like Oser, Mayo Robson, Kehr and Carrot, Borri as well as Michailow, arrived at the conclusion that many cases of catarrhal jaundice are not due to biliary disease but to a disturbance in the pancreas. Carrot who studied these cases most carefully, states as follows: "The finding of fat and muscle fiber in the stool, the absence of trypsin and presence of biliverdin in the stomach contents after an oil breakfast speaks against a pappillitis catarrhalis, but rather for what Carrot terms acute angiopancreatitis, and which responds favorably to the use of laxatives." A bronze coloration of the skin has been observed by many, Albu found several times interstitial changes in the pancreas in bronze diabetes. This explains to us more than anything else the reason for finding sugar in the above disease.

The aid of palpation in the diagnosis of diseases of the pancreas is still unsatisfactory. Some observers, especially Hausman with his skillful palpation, claims to be able to feel even a normal pancreas in 0.5 per cent. Adolf Schmidt states that he never felt a normal pancreas, and many competent authorities agree that even an inflamed pancreas can only be made out in very thin persons. It was the experience of the writer that even in cases where every sign and symptom pointed to a tumor of the pancreas, no mass outside of the large gallbladder could be felt. The most easily palpated ones are the cystic tumors of the pancreas, but even here one can readily be misled by the fact that at one time the mass may be felt and at another not, like in a case cited byAlbu, who attributed it to the fact that the cyst emptied and refilled at intervals. The case of pancreatic cyst seen by me was so large and filled out the entire left hypochondrium that I mistook it for an ovarian cyst; even at the operation by A. V. Moskowitz, the origin of the cyst was determined with difficulty. A case of pancreatic cyst also discovered at operation as a result of trauma was reported by the late A. E. Isaacs. Recently I have had occasion to see a case in the service of Geheimrat Kraus in a woman forty years of age with a typical history of ulcer of the stomach in whom, in addition to the ulcer, a mass was felt in the left of the abdomen. The most painstaking examination could not establish an exact diagnosis. At the operation by Hildebrand a chronic ulcer of the pylorus and a cyst of the pancreas with a very thick capsule were found. Repeated examination for the presence of glucose in the urine should not be neglected, maltose has also been found by Rosenheim and Flatow. Alimentary glycosuria, the adrenalin mydriasis, and the other functional tests as described above should be applied.

Special Diagnosis.—Pancreatic apoplexy, and acute hemorrhagic pancreatitis have so many symptoms in common that they should be described together. They come on suddenly with severe abdominal pains, distension of the abdomen, absolute constipation, marked tenderness and rigidity of the upper quandrant of the abdomen, no leucocytosis and absence of temperature. The symptoms simulate a great deal ileus, general peritonitis, and perforation of abdominal viscus. I was once very much impressed by a correct diagnosis made by Dr. Leo Buerger at the Har Moriah Hospital because he paid particular attention to the rigidity, distention, and marked tenderness of the upper quadrant of the abdomen, in addition to the shock of the patient. It seems to me that in the future we ought to make use in the above-named diseases of the Noguchi Wohlgemut test which consists in examining the urine for diastase as suggested originally by them for rupture of the pancreas.

Abscess of the Pancreas.—This disease is not infrequently met with. Numerous cases have till now been reported by American, English, and German authors, notably amongst whom are Musser, the Mayos, Moynihan, Brugsch, and others. This disease, although setting in abruptly, is preceded by some gastric symptoms like pressure in the epigastrium, slight icterus, nausea, and irregular temperature and the positive functional tests in the stomach contents and stools as well as the presence of sugar in the urine will lead one to a correct diagnosis. A case that I saw operated by Hildebrand was diagnosed correctly by Brugsch because he pair particular attention to the laboratory examinations of stomach contents and stools. A palpable tumor is a rare occurence, but it has been observed by some.

Cirrhosis Pancreatica.—The symptoms are those of intermittent gastric disturbances, slight icterus, pain varying in severity in the upper portion of the abdomen and the positive stool examinations as well as the occasional finding of sugar in the urine and the positive test for alimentary glycosuria.

Fat necrosis of the pancreas has all the symptoms of hemorrhagic pancreatitis with the exception that the acute symptoms subside and there are free intervals. Many authors found necrosed tissue of the pancreas in the stools.

Stones of the pancreas give rise to symptoms when the ducts become obstructed and parenchymatous changes take place in the pancreas. The disease is often associated with cholelithiasis and fre-

quently leads to atrophy, abscess, and fat necrosis. The colicky attacks are not easily differentiated from renal and biliary colic. The differential points are the following: even in the intervals there is always some pressure pain in the region of the stomach, the pains radiate to the left hypochondrium and there is more severe bilious vomiting. Above all, diabetes is more frequent in this affection than in any other pancreatic disease, or, there is at least glycosuria present during the attacks. There is no bile, urobilin or urobilinogen in the urine. Eichhorst lays stress on the presence of salivation in this affection.

Cysts of the pancreas are quite frequent and of practical value, as surgical interference leads in this affection to better results than in any other disease of the pancreas. They are palpable after they have attained the size of a plum; they are likely to grow and contain many quarts of fluid. Objectively, there is a mass above the umbilicus not movable with respiration and of a smooth and elastic character by insufflation of the stomach and intestines, disease of these organs can be excluded. Sometimes the swelling may entirely disappear by emptying itslf into the intestines and reappear when they refill. (Albu). If the cysts sit at the head of the pancreas they may cause jaundice by pressure on the ductus choledochus or hydrops of the gall bladder by pressure on the cystic ducts or both by pressure on both ducts. There may also be pyloric or duodenal stenosis on account of pressure. Disturbed intestinal absorptive power may give rise to emaciation. On the other hand, creatorrhea, steatorrhea, diabetes, alimentary glycosuria, and absence of trypsin are but seldom observed in this affection.

Carcinoma of the Pancreas.—This is the most frequent of pancreatic diseases, very often primary, sometimes secondary. The symptoms may be divided into: (a) Where there was no symptoms during life and the disease was accidentally discovered at autopsy, the disease involving but a small part of the gland. (b) Where there is severe digestive disturbance, rapid emaciation and cachexia, which are no characteristic signs of pancreatic disturbance. (c) Cases with fat stools, positive specific reaction, acetonuria, and glycosuria. (d) Cases where compression of the ductus choledochus leads to jaundice, and where there is at the same time compression of the cystic duct leading to hydrops of the gall-bladder. (e) Cases where compression of the pylorus or the beginning part of the duodenum gives rise to symptoms of pyloric obstruction.

Syphilis of the pancreas occurs either in the form of gumma or as interstitial changes. The diagnosis is clinically only possible when there is evidence of disease of the pancreas plus syphilitic manifestations in other parts of the body and a positive Wassermann. Tuberculosis of the pancreas was observed by many in association with tuberculosis elsewhere.

Atrophy of the pancreas is more of pathological and anatomical interest, because its recognition in life is not yet established. A few cases have been reported in the literature in which severe diabetes, with marked digestive disturbances, especially with bulky clay-colored voluminous stools were present, which led to a diagnosis during life.

I must in brief make reference to the pancreatic diarrhea described by Ehrmann, which is to be differentiated from the diarrhea of intestinal origin and that due to achylia gastrica. He found that in this form of diarrhea trypsin is frequently absent in the stools, steapsin diminished in the stomach contents and pancreon has a favorable influence.

Prognosis.—It is as yet quite difficult to be very definite as to the prognosis of pancreatic affections. It is certain that the medical diseases of the pancreas are frequently well influenced by treatment and some even entirely cured. Of the surgical affections the hemorrhagic pancreatitis and apoplexy of the pancreas, necrosis, cancer, and sarcoma of the pancreas are the most unfavorable. Abscess of the pancreas is more favorable, the same is true of stones, most of all are the cysts.

Etiology.—Of the real etiological factor but little is known. From surgical and post-mortem statistics we learn that trauma syphilis and above all diseases of the gastrointestinal tract, the liver and biliary passages are predisposing factors. So frequently is the pancreas found diseased post-mortem that surgeons are inspecting the pancreas now whenever they operate on the stomach, duodenum or biliary passages. Gallstones predispose to disease of the pancreas in the following manner: they cause pressure on the ductus choledochus, which in turn obstructs the pancreatic duct, producing stasis in the pancreas which leads to bacterial invasion. As the result of infection the nonactivated ferments become active, leading to destruction of the pancreas. It is reasonable to assume that trypsin causes the hemorrhagic form and steapsin fat necrosis. Duodenal ulcer causes pancreatitis by extension. Arteriosclerosis and alcoholism are predisposing factors, the latter surely by its primary toxic action on the liver. Stones of the pancreas are due to obesity, diathesis and atony of the bowels. Abscess of the pancreas is often the result of suppurative processes in other organs of the abdomen or in pyemia. In the case of Brugsch mumps preceded the disease.

Treatment is divided into medical and surgical. To the former belong chronic pancreatitis, catarrh of the pancreatic ducts, and the cases of pancreatic diarrhea. Our treatment must be directed to the outcome of the functional tests, the results of the urinary examination and the condition of the digestive organs. The most important consideration is the dietetic one. In cases where muscle fibres and fat are found in the stools we should give meats very sparingly, well cooked, and finely chopped. The white meats and soft fish are to be preferred. Vegetables, such as spinach, carrots, spring beans, asparagus, mashed potatoes are allowed. Fats should be avoided and even milk given only well diluted or butter milk kephyr zoolak should be substituted.

Carbohydrates should be used sparingly, even in cases where there is no sugar in the urine. If there is sugar in the urine, the dietetic problem becomes still more complicated as pancreatic diabetes is usually of a very severe nature and associated with acetone and diacetic acid. We must therefore not interdict all carbohydrates, vegetable, and oatmeal days should be instituted at regular intervals, and large doses of bicarbonate of soda given internally. A few words yet about the congenial idea of Wohlgemut as to the diet which is important in many forms of the disease, especially when we want to limit the secretions of the gland. Based on the findings of Pawlow that CH causes in the fistulous dog the greatest flow of pancreatic juice, Wohlgemut advises a strict antidiabetic diet with large doses of bicarbonate. He succeeded to

cure a fistula that followed an operation for a cyst of the pancreas that persisted for one and three-quarters of a year and prevent a fistula in another case.

Of drugs there is nothing specific. Laxatives are recommended by many, and the one that is of service is calomel. It should be used at least once a month in divided doses up to 0.3 gram. Of the ferments the only ones that enjoy some reputation are pancreon and pancreatin in doses of 0.5 gram t.i.d., the former is preferred because its acts in an acid and alkaline medium. Where the bronze color is marked we may try adrenalin solution 1:1000, 10 drops t.i.d.

Tonics are also of value, and the same is true of advising the patient to spend some time at one of the spas like Saratoga Springs, Carlsbad, Kissengen, and so forth. Where syphilis is suspected specific treatment should be instituted. For the outcome of surgical diseases the earlier the diagnosis is made and surgical intervention practised the better the results. Until now operative results have already yielded quite a percentage of recoveries and it should be the duty of every practitioner to have such cases operated on as early as possible.

Medicolegal Notes.

Administration of Narcotics Causing Death—Involuntary Manslaughter.—It is a penal offense to give, furnish, or sell any of the narcotic drugs mentioned in the Georgia Statute, Acts 1907, p. 121, Civ. Code 1910, § 1651, namely, cocaine, alpha- or betaeucaine, opium, morphine, heroin, chloral hydrate, or any salt or compound thereof, except upon the prescription of a lawfully authorized practitioner of medicine, dentistry, or veterinary medicine. This statute was intended, not only to prevent traffic in such drugs, but also to lessen the evils consequent upon the habitual use of such narcotics. Where a person, in violation of the statute, administers, by means of a hypodermic syringe, morphine to another in such quantity as to cause death, it is held that he commits an unlawful act, and a conviction of involuntary manslaughter in the commission of an unlawful act would be authorized. It would be no defense that in the administration of the drug the intent was not to cause death, but to alleviate pain.—Silver v. State, Georgia Court of Appeals, 79 S. E. 919.

Admission of Licentiates of Other States—West Virginia Regulations.—Section 9, Chapter 150, of the West Virginia Code 1906, as amended and re-enacted by chapter 66, Acts of 1907 (Code Supp. 1909, c. 150), vests "the State board of health of West Virginia" with discretion to make reasonable rules and regulations respecting the granting of licenses to medical licentiates of other States with whose licensing authorities it has established reciprocal relations, and to refuse to grant licenses to those who have not complied with such rules and regulations. In an action of mandamus to compel the board to issue to the applicant, a licentiate of the State of Maryland, a license to practise within the State of West Virginia, it was held that a rule or regulation which requires a foreign medical licentiate to reside and practise his profession in the State which licensed him for one year before making application in West Virginia is reasonable, and the failure of the applicant to comply with it will justify the State board of health in refusing him a license. The year's practice in the foreign State must be in compliance with its laws. The interpretation given by the said board to a rule or regulation adopted by it will be followed by the court. Thomas v. State Board of Health, West Virginia Supreme Court, 79 S. E. 725.

Failure To Effect a Cure No Inference of Negligence.—In an action for alleged malpractice consisting of careless and negligent diagnosis and treatment of the plaintiff's dislocated shoulder, it was held that negligence could not be inferred or presumed from the failure to effect a cure, and that the condition of the plaintiff's shoulder subsequent to the plaintiff's treatment did not of itself establish an inference that the plaintiff had been negligent in his treatment.—Hoffman v. Watkins, Washington Supreme Court, 138 Pac. 664.

Practising Medicine without a License—Penalty.—A statement of claim for a second conviction for practising medicine without a license stated that the claim was for $200 for a penalty as provided for a subsequent offense of a violation of chapter 91, paragraph 13, Hurd's Illinois R. S. 1911, that it was the contention of the plaintiff that the defendant had practised medicine as defined in section 7 of said act without a license as provided for in sections 2 and 3 of the act, that the offense was committed in Chicago on or about a certain date, and that the defendant had been previously convicted of the offense. It was held that the statement was sufficient on which to base the claim.—People v. Fairfax, 181 Ill. App. 436.

Homicide—Negligent Operation by Physicians as a Defense.—On a trial for homicide it appeared that, as the result of the wound inflicted by the accused, hospital physicians performed an operation with a view to improving the condition of the patient and saving his life. This was unsuccessful, the patient dying within a few hours. There was no claim by the defense that the deceased had recovered from his wound at the time of the operation, or that there was any evil intent in performing the operation, or that it was performed for any other purpose than an attempt to save life. It was held that it was not available as a defense that the operation was not performed in such manner as a reasonably prudent doctor would have performed it.—State v. Gabriella, Iowa Supreme Court, 144 N. W. 9.

IMMODERATE SMOKING AND THE CARDIO-VASCULAR SYSTEM.

THERE is abundant clinical evidence that excessive smoking causes certain neuroses of the heart and is a potent factor in the production of arteriosclerosis. The experimental study of the effects of nicotine when injected into rabbits has shown that this alkaloid gives rise to the various changes of arteriosclerosis. This knowledge is not likely to deter the confirmed smoker. Nevertheless, it furnishes a rational argument for the restriction of this form of indulgence.

A comprehensive study of the effects of tobacco upon the heart and blood vessels is contributed by J. Pawinski to the *Zeitschrift für klinische Medizin*, Vol. 80, Nos. 3 and 4. In studying the causes of arteriosclerosis as revealed in 3,156 cases with a known etiology, the author found that immoderate addiction to tobacco occupied the second place, the first being obesity. A history of excessive smoking was recorded in 29.8 per cent. of the cases. There were 1,075 cases in which sclerosis of the coronary arteries was the most pronounced type of the disease, and in these cases tobacco came first in importance as an etiological cause, contributing to 41.9 per cent. of the cases, while obesity, alcohol, psychic manifestations, and syphilis came next in order, accounting for 26.3, 21.3, 13.3, and 10.3 per cent. of the cases respectively. In the 2,081 cases of arteriosclerosis in which the coronary arteries were not affected, the figures were as follows: obesity, 25.9; smoking, 23.3; alcohol, 23.3; syphilis, 13.3, and psychic causes, 6.1. The significant fact gleaned from these statistics is that of those patients who suffered from angina pectoris about one-half had been inveterate smokers, whereas in the cases of arteriosclerosis without angina pectoris only one-quarter of the patients had been addicted to tobacco. The above figures applied to cases in which in addition to the main etiological cause there were other associated factors. The figures were much smaller when the causes were not combined. For instance, when smoking was the only possible etiological factor it accounted for 19.4 per cent. of the cases of coronary sclerosis instead of for 41.9 per cent. The ratio of the simple to the combined factors was 209:248. On the other hand, in the remaining vascular territory the ratio of the tobacco factor alone to this factor combined with others was 316:370. From these data the important conclusion is drawn that tobacco has a certain, possibly a specific affinity for the coronary arteries and may probably be compared to the psychic factor, which plays an important rôle in the pathogenesis of angina pectoris. The factor which, in combination with tobacco, appears to be most frequent in the etiology of arteriosclerosis is alcohol; and this is particularly the case when this condition is generalized.

Nicotine is a powerful poison which approaches cyanogen very closely in its virulence. The fatal dose for human beings has not been determined, but doses as small as 0.001 to 0.003 gram cause serious symptoms of poisoning. In addition to nicotine, tobacco leaves contain a nitrogenous substance, nicozyanine, related to camphor, and resembling nicotine very closely in its action. In addition these leaves contain volatile oils, nitrogenous substances, fat, organic acids, starch, sugar, pectin, and cellulose. The much-disputed question whether tobacco smoke contains nicotine has been decided in the affirmative by the investigations of Zulinski and Zebrowski. Tobacco smoke contains in addition two other bases belonging to the pyridin groups, namely, pyridin and collidin. Pyridin is formed chiefly if the tobacco is smoked in a pipe and irritates the mucous membranes; collidin is formed chiefly when the tobacco is smoked in cigarettes and has a milder action.

Claude Bernard was the first to prove that nicotine is a poison to the vagus nerve. Traube showed that nicotine has an action closely allied to that of digitalis, both substances exciting the neuromotor apparatus of the heart. Recent investigations have shown that nicotine has a pronounced action upon the muscle fibers of the heart. Besides it has a marked action upon the blood vessels, causing a considerable rise in the blood pressure. This is the result of a stimulation of the vasomotor center in the medulla oblongata and the vasomotor apparatus in the wall of the blood vessels. The vessels chiefly of the lower extremities and of the abdominal cavity are contracted, but the cerebral vessels are dilated. Following a period of increased blood pressure there is a reduction of the pressure below the normal.

Langley and Anderson have shown that nicotine is a potent poison for the cells of the entire vegetative nervous system, including both its sympathetic and its autonomous divisions. In this respect nicotine is unlike other exogenous poisons, whose specific action is more restricted. For instance, suprarenal extract exerts its influence only upon the endings of the sympathetic nerves, while atropine and muscarine act only upon the peripheral ends of the autonomous nerves. Pezzi and Clerc studied the action of nicotine upon cardiac rhythm and attributed the irregularities in the latter induced by this alkaloid to its excitation of the vagus center. In this connection the experiments performed by Otto on rabbits are of eminent clinical significance. He found that the most marked changes occur in the coronary arteries and its branches, and consist in a considerable thickening of the intima and in a pronounced degeneration of the media. Besides, the heart

muscle undergoes parenchymatous and interstitial changes. The investigations of Adler and Hensel of New York must not be forgotten, for these observers succeeded in producing atheromatous changes in the aorta by means of intravenous injections of nicotine.

The functional disturbances of cardiac activity which are attributed to the effect of nicotine are similar to those that result from other causes, such as brain-fag, neurasthenia, hysteria, etc., with this difference: in the former the disturbances of rhythm are particularly the occurrence of intermissions caused by extrasystoles. In men these disturbances occur after about ten or more years of indulgence in smoking. A persistent irregularity is more rarely observed occurring particularly in habitual cigar smokers who also eat and drink to excess, and in obese individuals. The sensory neuroses of the heart resulting from tobacco are more common in women than in men. Precordial anxiety and bradycardia occur only in those who smoke greatly to excess, and paroxysmal tachycardia occurs in those who inherit an unstable nervous system. Attacks of false angina pectoris are also attributed by the author to immoderate smoking. The sclerosis of the vessels of the lower extremity is another sequence of this habit. It gives rise to intermittent claudication, which in certain respects is regarded as a peripheral form of angina pectoris. The so-called angina abdominis is likewise attributed to the same cause.

REPRODUCTION AND RACE BETTERMENT.

In a discussion on Reproduction and Race Betterment, published in the Pennsylvania Health Bulletin for February, 1914, Dr. Samuel Dixon, Commissioner of Health for that State, points out that society absolutely requisite for the continuance of our present civilization is divided into domestic and civil. Dealing with the former the hygiene of married life must be considered and this brings up the point with regard to the suitable age and conditions of life at which the bonds of matrimony may be assumed. The writer lays down the following rules as to marriage: First, a man should not marry unless into a family with a history of reasonable longevity, free from hereditary disease. He should not marry a woman advanced in life, delicate, feeble, or afflicted with any inherited deformity. The age most proper for women in this climate is nineteen or twenty years and for men twenty-four or twenty-five years. Women of a nervous temperament, those who are extremely irritable, hysterical, subject to convulsions, or to epilepsy from organic disease, ought to avoid matrimony. In this country matrimonial contracts between the sexes before the ages of twenty-five and nineteen respectively, are contraindicated because, as a rule, previous to these periods of life, the body is not fully developed, the different functions are not perfect, and the sexual organs being only in progress of their growth, any offspring developed by them in their immature condition, must be deficient in vital power.

The author states that according to an eminent authority, the principal sources of degeneracy, which appear at present to be most active in the world in their influence for evil on large masses of mankind may be grouped as follows: (1) Degeneracy from toxemia, or from the abuse of alcoholic fluids, opium, preparations of Indian hemp, preparations of coca, tobacco, and the like; also from the effects of lead, mercury, arsenic, and phosphorus, and from the use of unwholesome vegetable food, such as diseased rye, maize, wheat, and the like. (2) Degeneracy from the persistent pernicious influence of malaria. (3) Degeneracy from certain peculiar geological formations, soil, and water, as seen in the development of goiter. (4) the generations which follow the one which has and then afflict large populations, profoundly influencing the system, and engendering those morbid temperaments whose types are fully expressed in those generations which follow the one which has suffered from such epidemic pestilences. Many such epidemics act like toxic agents on the nervous system. (5) Degeneracy from the effects of the great town system, as it is called. The chief elements of such degeneration are unhealthy situations, a noxious local and general atmosphere, insufficient air, insufficient and improper nourishment, deleterious avocations, moral and social misery, and crime. (6) Degeneracy from fundamental morbid states, congenital or acquired, as seen in imperfect cerebral developments, deaf-mutism, blindness, constitutional diseases and diatheses, implanted, hereditary, or acquired, such as syphillis and scrofulosis. (7) Degeneracy from mixed causes, from consanguineous marriages. It will be gathered from a study of the above conclusions that heredity and environment would appear to exert almost equal influences upon the production of degeneracy. Probably, this is indeed the case.

SYMPTOMS OF UREMIA AND THEIR INTERPRETATION.

The symptoms of uremia are diverse and varied owing perhaps to the fact that more than one poison is concerned in the production of this complex. Dr. H. B. Anderson read before the Academy of Medicine, Toronto, on April 7, 1914, a paper on the subject which was published in the *Journal of Preventive Medicine and Sociology* for July. He pointed out that uremia has been classified clinically as (*a*) fulminating, (*b*) acute, (*c*) chronic, and (*d*) latent. In the first variety, the symptoms develop in their severest form with alarming rapidity and without previous warning. This variety is most frequent in recognized cases of granular kidney. The acute cases develop suddenly, but in cases in which other phenomena, such as albuminuria, greatly reduced quantity of urine, urea in the blood, or other evidence of impairment of renal function, would put one on one's guard as to the probable development of uremia. In the chronic type of uremia, gastrointestinal symptoms are often a marked feature, though headache, twitchings, cramps in the muscles, especially of the calves, general restlessness, pruritus, impairment of sight

or hearing, delirium, and eventually convulsions or coma, may appear.

The latest type, described by Sir William Roberts, occurs especially in double calculous pyelitis, with occlusion of both ureters, and consequently complete anuria. It has also developed where a compensatorily hypertrophied kidney has been removed, the other kidney being functionally inactive from disease. Apart from the nervous manifestations of uremia, the gastrointestinal are the most important and next to the alimentary tract the skin offers the most efficient route for the elimination of the poison. Frequently, the sweat of an uremic individual has a urinous odor. The respiratory system also exhibits evidence of the toxemia. Two abnormal types of breathing may be manifested: (1) A peculiar hissing type, sometimes called "goose-breathing"; this is a rare symptom. (2) Cheyne-Stokes breathing. The blood pressure is frequently though not invariably high, and Anderson insists upon its serious significance.

While so great importance is not now paid to uranalysis as formerly it is an error to consider this mode of diagnosis as of small moment. Generally speaking a more favorable view is taken of uremic symptoms than used to be the case, and much depends on the patient's general condition. The purely renal aspects of the case are not considered of altogether supreme moment.

The Relation of Movable Kidney to Chronic Appendicitis and Cecum Mobile.

As is often the case with movable kidney, an unusually mobile cecum may exist without giving any symptoms. Usually, however, it is only after a considerable amount of experience that the fact is sufficiently impressed upon a surgeon that the degree of mobility *per se* may bear very little relation to the severity of the symptoms. A slightly movable kidney may be accompanied by the entire chain of reflex digestive and nervous phenomena in one case, while there may be mobility to an extreme degree in another with no subjective symptoms whatever, and the loose kidney may be discovered quite by accident in the course of a routine examination of the abdomen. Many years ago Edebohls became impressed with the frequency of chronic appendicitis as a sequel of movable right kidney and finally published the results of his observations in a paper entitled "Chronic Appendicitis the Chief Symptom and Most Important Complication of Movable Right Kidney" (*The Post-Graduate*, February, 1899). The attention of surgeons once having been drawn to this sequence, confirmatory reports soon appeared in abundance. The coexistence of movable kidney and ptosis of other viscera has long been recognized; and since gastrointestinal derangements are a frequent result, these patients have been subjected to nearly every conceivable method of treatment. In 1901 Lane began removing the colon for the relief of chronic intestinal stasis due to ptosis of the hollow viscera. This procedure was so revolutionary that a storm of protest was at first aroused; but later many investigators undertook experimental and clinical work along this line. Among these, Coffee made an extensive study of the principles underlying the surgical treatment of gastrointestinal stasis and allied conditions, and called attention to the fact that in a very large number of cases where there is not a general enteroptosis but the right kidney is abnormally movable, there is also defective fusion of the cecum and ascending colon, with resulting prolapse and often dilatation of this portion of the gut. He therefore pointed out that in symptom-producing cases not only should the kidney be fixed and the appendix removed but the cecum and ascending colon should be firmly anchored.

A Study of Baseball.

The manner in which a people play is typical of their temperament, and therefore baseball may truly be termed the national game because it typifies the American temperament in the same way as cricket is typical of the English temperament; or, at any rate, it used to be so. Arthur Macdonald of Washington has published an article on the scientific study of baseball in the *American Physical Education Review* of March, 1914. The writer, who appears to have a very accurate knowledge of baseball, considers that the game is one of the greatest moral tonics for boys and young men that exists. It directs the surplus physical energy of youth into the right channel, for otherwise the energy might be employed in wrong ways detrimental to moral and physical life. The author discusses the anthropological features of baseball and has succeeded in composing an article interesting and to some extent instructive. All healthy games are beneficial and for this reason, he says, baseball properly conducted is to be heartily commended.

News of the Week.

Diagnosis of Cancer.—Because of a recent suggestion that the New York City Department of Health undertake the provision of laboratory facilities for the microscopical diagnosis of cancer, Dr. Harvey R. Gaylord, director of the State Institute for the Study of Malignant Disease at Buffalo, has written to the Commissioner of Health assuring him of the willingness of the Institute to undertake the diagnosis of all material from cases of suspected cancer sent to it from New York City. As the Institute is already equipped for such work and is prepared thus to cooperate with physicians throughout the State the City Health Department will take no further action in the matter.

The Boylan Law.—In response to repeated inquiries as to the duties of physicians under the Boylan law, the Health Department announces that prescriptions for chloral, opium, or any of its salts, alkaloids, or derivatives, or any compound or preparation of any of them may be written on ordinary prescription blanks. The prescription, however, must be dated, and must bear the name, address, office hours, and telephone number of the prescribing physician, and the name, age, and address of the person for whom the drug is prescribed. Physicians should also keep a record of all instances in which they personally administer any of the above mentioned drugs.

Rockefeller Gift Completed.—Title to the property of the Rockefeller Institute for Medical Research, New York, was transferred on July 6 by Mr. John D. Rockefeller, junior, to the corporation of the Institute. The property is the largest used by a medical institution in this city; it cov-

ers three full blocks, reaching from the north side of Sixty-fourth Street to the south side of Sixty-seventh Street, and from Avenue A to the East River, and is worth more than half a million dollars.

Care of Drug Users.—Under the Boylan law, which went into effect in New York on July 1, and provides for the commitment of habitual drug users to State, county, and city hospitals, the resources of the city will probably be taxed to the utmost. There are at present accommodations in the New York hospitals for not more than 100 such cases, and these provisions are only temporary. At a conference held on July 7 by those interested in the situation it was decided, therefore, to make use of the farm colony of the Department of Charities on Staten Island, where it will be possible to care for 150 patients, and at the same time it was agreed to urge upon the Board of Aldermen the desirability of providing structures on the city's farm for inebriates in Orange County, so that drug users can be treated there also.

Interborough's Medical Staff.—As the Workmen's Compensation Law, which has gone into effect in New York, requires that an employer shall provide an employee who has been injured while in his service with medical care and attendance, the Interborough Railroad Company of New York has made arrangements by which the workers on the elevated and subway lines will receive the best medical care possible. If necessary, the injured employee will be visited at his home by the company's doctor, who if it is thought wise will order his removal to a hospital where he will be placed in a "semi-private ward" and be permitted many liberties denied to the regular ward patients. It has also been arranged that some of the employees of the company shall be trained in first-aid work by the surgeons of the Interborough, so that immediate attention can be given to an injured person.

German Census.—According to the Imperial Statistical Office, Germany now has 67,812,000 inhabitants, the gain in the year being 831,000. Since 1904 the population of the country has increased by 8,337,000 or 14 per cent., while during the preceding decade the increase was at the rate of nearly 16 per cent.

Cornerstone Laid.—Impressive ceremonies attended the laying of the cornerstone of the new medical building of the National Jewish Hospital for Consumptives at Denver, Col., on June 28. The building is the gift of Mr. Samuel Grabfelder and will cost approximately $40,000. It will be a two-story brick and stone structure, and will contain a bacteriological laboratory, a drug room, quarters for the animals used in experimental work, etc.

Affiliation of Journal and Medical Society.—The *Boston Medical and Surgical Journal*, with its issue of July 2, 1914, began an official affiliation with the Massachusetts Medical Society, and will hereafter be the organ of the society. Such an association has been contemplated for some time past, and was consummated last month when a formal affiliation was voted by the councillors of the Medical Society. Dr. Walter L. Burrage and Dr. Frederick T. Lord have been appointed editors of the society to act in association with the editorial staff of the *Journal*, and an additional advisory board of four from the society will shortly be appointed to act with the three owners and Dr. Robert B. Osgood in relation to matters of policy and conduct of the paper. Such a union gives promise of a wider influence both for the society and for the journal in all matters pertaining to the progress of medicine, not only in Massachusetts but throughout all New England.

Civil Service Examination.—The United States Civil Service Commission announces an examination on August 10, 1914, open to both men and women, for the purpose of filling a vacancy in the position of expert on Sanitation in the Children's Bureau, Department of Labor, Washington, at a salary of $2,800 a year. The holder of the position will act as adviser of the Bureau in matters requiring knowledge of hygiene, and, in cooperation with other experts, will conduct investigations into dangerous and injurious occupations, the social factors responsible for high infant mortality, and other matters involving health. Competitors will not be assembled for examination but will be rated according to the following schedule: Education, 40 weights; experience, 40; publication of thesis, 20. Graduation from a recognized medical school, and at least three years' specialization in the hygiene and diseases of childhood or three years' experience in sanitary inspection work are prerequisites, and applicants must be between twenty-five and fifty years of age. Persons desiring to take the examination should apply at once to the United States Civil Service Commission, Washington, D. C.

Pennsylvania State Examinations.—As a result of the recent examination held by the State Board of Medical Examiners, sixty-five out of seventy-eight applicants have received licenses to practise medicine in the State of Pennsylvania.

Philadelphia Polyclinic.—The following changes and additions to the staff have recently been made: Dr. Thomas B. Holloway has been elected professor of ophthalmology in succession to Dr. James Thorington, resigned, and Dr. Charles R. Hood has been appointed associate professor of ophthalmology, and Dr. George S. Crampton, lecturer on refraction.

City Death Rate.—For the week ending July 4 the Health Department recorded the lowest death rate in the history of New York, 10.84 per 1,000 of population, representing a total of 1,160 deaths. The lowest previous record was 11.42 per 1,000, and for the corresponding week of 1912, the death rate was 12.54 per 1,000, while in 1901, when there was intense heat during the same period, the rate was 40.82. The decrease this year occurred in all the age periods, the number of deaths being 37 less among the infants under 1 year of age, 51 less among those between 1 and 5, 30 less between 5 and 65, and 13 less over 65 years. The death rate for the first 27 weeks of this year was 0.30 less than that for the same period last year.

The Plague in New Orleans.—The fifth case of bubonic plague was reported in New Orleans on July 12, the patient being a negro woman who was employed in a restaurant within two blocks of the house where the first case was found. Although approximately 4,000 rats have been examined in New Orleans since the first appearance of the disease, no infected ones have been found.

Rats Free from Plague.—The New York Department of Health reports that during the last few weeks a number of rats of the varieties known to be carriers of the plague bacillus, have been captured along the water front of New York and

examined; and that all of them have proved to be free from the infection.

Smallpox on Steamship.—Because of the occurrence of a case of smallpox in the steerage the Hamburg-American steamer Batavia which reached New York on July 5 was detained at Quarantine. The patient was sent to Swinburne Island and 77 passengers were transferred to Hoffman Island for observation.

Home for Babies.—The Haven, a new home for babies at Far Rockaway, L. I., will be opened early in August to care for the children of mothers who are ill in hospitals or are convalescing. It will have accommodations for 15 children and will be supported by voluntary subscriptions.

Personals.—Dr. ELMER B. COOLEY of Danville, Ill., has announced his candidacy for the Republican nomination for Congress from his district, in opposition to Joseph G. Cannon.

Dr. JOHN WALTER PERKINS, professor of surgery in the University of Kansas, has been elected chief of staff of the new St. John's Hospital at Salina, Kan.

Dr. OSCAR TEAGUE has been appointed by the Health Officer of the Port of New York, to serve as director of the new bacteriological laboratory recently completed at the Quarantine Station. Dr. Teague has had a wide experience in the diagnosis of plague, cholera, and other quarantinable diseases, which will make him particularly valuable in his new post. He served in the Bureau of Science at Manila for several years, and in 1911 was sent to Mukden as the American delegate to the International Plague Conference.

Gifts to Charities.—Mount Sinai Hospital, New York, receives $1,000 by the will of the late Isidore Wormser, Jr., of this city, and a like amount by the will of the late Adolph Magnus also of New York. By the latter will also the sum of $1,000 is bequeathed to the Montefiore Home, New York.

The Lying-In Hospital and St. Rose's Home, New York, receive bequests of $5,000 and $3,700 respectively by the will of the late Miss Lilla Gates.

Through a recent decision of the Appellate Division of the Supreme Court of New York, the Sea Breeze Hospital loses a bequest of $50,000 given to it in the will of the late Mayor Smith Ely of this city. The codicil containing this and other charitable bequests was signed by Mr. Ely only eight days before his death and was, therefore, declared by the Court to be invalid.

XIV^e Congres Francais de Medecine.—This congress will meet in Belgium on September 30 to October 1, 1914, under the presidency of Dr. Henrijeau, professor in the Faculty of Medicine at Liége. At the general sessions of the congress, the following subjects will be discussed: Syphilis of the heart and vessels; vaccine therapy, especially that of cancer and of typhoid fever; therapeutic value of artificial pneumothorax; lipoids in pathology. Further details may be obtained from the Secretary-General, Dr. René Verhoogen, professor in the Faculty of Medicine, Brussels.

Medical Society Elections.—AMERICAN MEDICAL EDITORS' ASSOCIATION. Annual meeting at Atlantic City, N. J., June 22, 1914. *President*, Dr. H. Edwin Lewis, New York; *First Vice-President*, Dr. H. D. Holton, Brattleboro, Vt.; *Second Vice-President*, Dr. W. M. Brickner, New York; *Secretary-Treasurer*, Dr. Jos. MacDonald, Jr., New York.

FULTON COUNTY (N. Y.) MEDICAL SOCIETY: Annual meeting at Hickman on June 23. Officers elected: *President*, Dr. John W. Naylor, Cayce; *Secretary-Treasurer*, Dr. Seldon Cohn, Fulton.

DALLAS (TEX.) MEDICAL AND SURGICAL SOCIETY: Annual meeting on June 27. Officers elected: *President*, Dr. O. M. Marchman; *Vice-Presidents*, Dr. J. H. Black and Dr. John R. Worley; *Secretary*, Dr. Frank A. Pierce; *Treasurer*, Dr. J. N. Coble.

National Mouth Hygiene Association.—At the concluding session of the annual meeting of this association held in Rochester on July 11, the following officers were elected: *President*, Dr. Harvey W. Wiley, Washington; *Vice-Presidents*, Dr. W. A. Evans, Chicago; Dr. Oscar Dowling, New Orleans; Dr. William R. Malone, New York, and Surgeon-General Rupert Blue, Washington; *Secretary-Treasurer*, Dr. G. Ebersole, Cleveland.

Obituary Notes.—Dr. ARTHUR FRANCIS EIFE of New York, a graduate of the New York Homeopathic Medical College and Hospital in 1881, and a member of the New York State Homoeopathic Medical Society, and the American Institute of Homeopathy, died at his home in Elmhurst, L. I., on July 7, aged 52 years.

Dr. JAMES HOWARD WILKES of Columbia, Tenn., a graduate of the University of Nashville, Medical Department, in 1862, assistant surgeon in the Confederate Army during the Civil War, and a member of the Tennessee State and Maury County Medical Associations, died at his home on June 20, aged 83 years.

Dr. GORDON CHITTOCK of Jackson, Mich., a graduate of the Rush Medical College, Chicago, in 1851, died at his home on June 23, aged 87 years.

Dr. WILLIAM GOVANS RIDOUT of Annapolis, Md., a graduate of the College of Physicians and Surgeons, New York, in 1866, died at his home on June 30, aged 77 years.

Dr. EDWIN DARLING of Vail, Ia., died at his home on June 20, aged 75 years.

Dr. PAUL SHERMAN of Shawneetown, Ill., a graduate of the College of Physicians and Surgeons, St. Louis, Mo., in 1888, and a member of the American Medical Association and the Illinois State and Gallatin County Medical Societies, died at his home from nephritis on June 16, aged 39 years.

Dr. NAPOLEON B. MORRISON of Wilmington, Del., a graduate of the Jefferson Medical College, Philadelphia, in 1857, died at his home on June 26, aged 80 years.

Dr. MICHAEL JOSEPH BROWN of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1896, died at his home on June 26, aged 70 years.

Dr. HENRY PATTERSON, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1879, died at his home in Wilmington, Del., on June 30, aged 60 years.

Dr. D. E. MCEACHERN of Statesboro, Ga., a graduate of the Medical College of the State of South Carolina, Charleston, in 1894, and a member of the Medical Association of Georgia and the Bulloch County Medical Society, died suddenly while attending a patient, on June 26, aged 40 years.

Dr. WILLIAM T. RINEHART of Ashland, Wis., a graduate of the Jefferson Medical College, Philadelphia, in 1886, and a member of the American Medical Association, the State Medical Society of Wisconsin, and the Ashland-Bayfield-Iron Counties Medical Society, died at a hospital in Chicago, where he had gone for treatment, on July 2, aged 59 years.

RELATION OF SCIENCE TO THE STATE—ST. THOMAS'S HOSPITAL PRIZES; SIR C. ALLBUTT ON THE FUTURE DOCTOR—CARE OF DEFECTIVES—UNION OF NON-PANEL PRACTITIONERS—GERMAN HOSPITAL—LEPER HOSPITAL FOR ENGLAND—GIFTS TO CHARITIES.

London, July 3, 1914.

A NEWSPAPER correspondence on the relations between "Science and the State" has been going on for several weeks. A number of representatives of science have pressed its claims on public support. Some of them urge that successful discoverers might properly be awarded titles and decorations, while others declare that the joy of research is its own reward and science might suffer if it offered a prospect of a "fat living." In opposition to this view it has been remarked that the best brains are being attracted to commerce by the ample rewards it offers. Nearly all the correspondents plead for subsidies in some form or other, but a small minority deprecates any endowment from state or municipal funds. The question how the State—if it were to undertake to provide financial aid—should proceed has been discussed as a subsidiary one—and has elicited many differences of opinion. The majority advocate additional endowments to the universities to enable them to increase the inadequate stipends of professors and lecturers and to establish new chairs for research. Others would rather organize special institutes for research and praise the work of the "scientific advisory committee on aeronautics," which is unhampered by officialism. The apathy of the State—so generally lamented—which should perhaps be called rather the apathy of politicians, is not likely to be overcome by discussion. Results will be asked for and when they are shown to be of importance to the democracy many difficulties will be thrust aside and expenditure incurred which can be seen to be profitable. In medical claims sanitation has obtained recognition among all classes as essential to the prosperity of the country. Another illustration of what might be accomplished if sufficiently supported is the success that has followed every step taken for the advancement of tropical medicine.

At St. Thomas's Hospital, the treasurer, Mr. Wainwright, presided at the distribution of prizes on Tuesday and in a short address said they were setting apart research wards to be under the staff and professors. They had also engaged to purchase radium to the value of £8,000. The Insurance Act had relieved them of a large number of trivial cases, but had increased the expenses in other departments. The tuberculosis dispensary had proved of great value to patients and to students as had another new department, neurology. The "baby clinic" had increased beyond measure and afforded valuable experience to students and instruction to mothers. In the past year 9,267 cases were admitted to the wards, being 495 more than in any previous year.

Sir T. Clifford Allbutt gave the prizes and proceeded to enliven the audience with one of his genial speeches, telling the young men how glad he was to see them still, like a pack of hounds following a breast-high scent in full dash after the subtle quarry of truth. It was the joy of the older generation to feel that the results of the last half century would be carried on even more brilliantly by their successors. The advance was due to science, but it would not be all for the best for men of science to have all their own way. Practical men said there was something more than analytical knowledge—called science. Why had the practical man such contempt for the young man fresh from the schools? In the art of medicine there was in fact a something more than analytical knowledge could give. The training of hand and eye gave a certain facility and power. The young man might think his elder a duffer, but young and old were necessary to each other. Even in the laboratory the skilled hand could by instinct do more than one with only theoretical training. But practical men were under the disadvantage of having no grip of principle. Their mind was not flexible; it was all right for to-day, but not for to-morrow. Small revolutions in practice meant the scrapping of old methods. Sir Clifford went on to refer to the changes impending in general practice. The panel practitioners he thought should have power to command any specialist aid they needed. That would lift English medicine to a higher level. The time of medicine was coming when it would reach the social consideration it deserved. Cambridge had been first in this country to establish a research hospital. The committee for national research were talking of setting up another; meanwhile St. Thomas's Hospital was nipping in to be second and he congratulated it most cordially on the new effort. Sir Clifford also referred to the need of a ministry of health—an office which he had urged as necessary ever since he spoke in public and which a member of the government had just said was wanted. He also held the study of comparative medicine was needful. Everything was centered at present in man-medicine, whereas, if great progress was to be made the medicine of the gooseberry bush should be studied.

A central association for the care of the mentally defective is being organized and the approval of the Board of Control has been expressed with an intimation of an intention to assist financially by a grant under the Mental Deficiency Act. The board hopes that the representative character of the Central Association and its inclusion of experts with special knowledge of metropolitan conditions will make it acceptable as the London association, also, in which event a substantial grant will be added in this respect. The Board of Control and the Home Secretary attach much value to the work that may be done for defectives and would gladly see efficient voluntary societies in every area, but as they could not possibly supervise constantly and closely the operations of all, they welcome the setting up of the Central Association, which can focus, co-ordinate, and disseminate the experience and knowledge acquired by all and advise them within the limits laid down by law or suggested by Providence.

The National Medical Union formed last December of men who decline to serve on the panel has now been completely constituted. On Monday it held its first dinner when one of the speakers expressed surprise that 12,976 practitioners were not on the panel, but 11,820 were in England alone. Adding Wales and Scotland the numbers were 15,663 not on and 14,472 on the panels. Those numbers suggest that the opponents of the system ought to be able to enforce great changes, but it is doubtful if general satisfaction will be attained, at any rate, for a long time. There is no doubt that

great numbers look on the panel as securing bread and cheese—they were taunted with this at the dinner. That it is a fact is common talk and the danger is deterioration of the professional status. One speaker said on telling a student he should learn for the sake of the profession the student would report it to his companions with the reply, "Profession be hanged—I can earn £1,000 a year with 3,000 patients on my panel."

Prince Lichnowsky presided at the sixty-ninth anniversary of the German Hospital last week. The hospital contains 174 beds and the medical staff has always held a good position. The benefits are not confined to Germans, for it stands in a district where accidents are not uncommon and English patients are freely admitted. Last year 2,358 in-patients and 22,522 out-patients were treated. Of the in-patients 537 were English, 150 were admitted into private homes set apart for a better class, and 353 were transferred to the hospital's convalescent home. The income of the hospital had been £7,000, but the expenditure amounted to £14,500, and the president made an appeal for the sum required to cover the excess. The German Emperor has given £200, the Austro-Hungarian Emperor £50, the chairman added £50.

A bequest of Lord Strathcona having been made for the establishment of a leper hospital in England, a farm has been taken for the purpose in Essex and plans prepared for a building. The farmhouse will be utilized in the meantime for some patients said to be in need of treatment. It is estimated that there are about twenty cases in England at the present time, five of them resident near London. It will not be limited to lepers, but skin diseases reputed to be incurable will be received. Twelve beds are to be provided as a beginning, others being added if found necessary and financial support available.

Mrs. Pritt, a widow said to have reached the age of 99, died on June 4 and bequeathed £20,000 to various benevolent and religious institutions. The residue of a large estate she left to Liverpool charities.

Mr. Edwin Tate has promised to St. Bartholomew's Hospital a capital sum of £5,000, the interest to be used to assist necessitous patients to obtain artificial teeth.

EXPERIMENTAL STUDIES ON NASAL ASTHMA—EXPERIMENTAL NEPHRITIS—IMMEDIATE PROSTHESIS IN CASES OF RESECTION OF THE LOWER JAW—A CASE OF HEART SUTURE.

VIENNA, June 18, 1914.

IN a series of experimental researches Grossman tried to determine the causes of the clinical symptoms of nasal asthma. He found that irritation of the nasal mucosa with induced currents causes a considerable disturbance of the function of the heart and in consequence there is an engorgement of blood in the pulmonary circulation, as the result of which the lungs increase in size. This can be proved by the increase of pressure in the thorax and by the low position of the diaphragm. The augmentation of the volume of the lungs is accompanied by a rigidity of the latter and this is the real cause of the embarrassed respiration. In animals breathing naturally an irritation of the nasal mucosa causes a second impairment of respiration. The inspiratory phase is embarrassed to the extent almost of its total inhibition. If the second branch of the trigeminal nerve is previously cut, the effect of the nasal irritation upon the pulmonary circulation and consequently upon the volume of the lungs is eliminated. This also occurs if both vagus nerves are cut through. One has to do therefore with a reflex arc, the centripetal branch of which is formed by the trigeminal nerve and the centrifugal branch by the vagus nerve. The inspiratory inhibition by irritation of the nasal mucosa cannot be arrested by cutting the vagus on both sides. Therefore there must be a direct communication of the trigeminal nerve with the phrenic nerve outside of the vagus, which communication forms a second reflex arc which comes into operation by irritation of the nasal mucosa. The results of experimental nasal irritation bear a striking resemblance to the clinical symptoms of nasal asthma and in all probability the same mechanism and causal connections exist in the latter condition. In the discussion Hajek questioned the existence of a rhinogenous asthma.

The attempts to produce an affection in animals similar to acute and chronic nephritis has heretofore been unsuccessful inasmuch as the experiments caused an injury of the tubular apparatus of the kidneys by means of certain poisons, such as uranium, cantharides, chromium, mercuric chloride, etc., but not of the glomerular and other vascular apparatus of the organ. Hitherto only degenerative processes have been produced and not inflammatory processes of the parenchyma. Bahr has produced an acute inflammation by injections of uranium nitrate into the renal arteries. His animals all died in the acute stage. Even the chronic renal lesions produced by means of the above-named poisons bear no resemblance at all to the secondarily contracted kidney in men. Wiesel and Hess succeeded in producing a genuine chronic and a genuine acute nephritis, which can to a great degree be compared to the forms occurring in men. They carried out their experiments with a combination of intraperitoneal injections of a 5 per cent. solution of uranium with intravenous injections of suprarenal extract. In the first phase of this artificial nephritis there are, besides a degenerative process in the tubular apparatus, a swelling of and an increase in the nuclei of the glomeruli and an exudation which is frequently hemorrhagic into the interior of the capsules with a compression of the loops and a desquamation of the capsular epithelium. At a later stage the above changes are more marked and there are a beginning hyalinization and a thickening of the intima. In the last stages the kidneys are macroscopically diminished and their surface is uneven. The parenchyma of the kidneys is transformed to a great extent into connective tissue which shows a fatty degeneration like the degenerated tubular epithelium. The mechanism for the development of hypertrophy of the heart is probably the following: Through the strong contraction of the vessels of the glomeruli depending on the administration of suprarenal extract, the uranium is caused to remain longer in the glomeruli, as the result of which a more intensive action of this poison results. In some cases of human nephritis the same mechanism may be operative.

As the result of resection of the lower jaw there occurs a pronounced mutilation which is remedied by immediate prosthesis. Other methods for covering the defect demand difficult operations, such as implantation of a fragment of bone from the tibia,

which operations subject the already weakened patients to considerable risk. Immediate prosthesis was recommended by Claude Martin in 1878. Eiselsberg resorted to this procedure in fifteen cases of resection of the lower jaw. The apparatus consists of hardened caoutchouc and has tubes with which it is cleansed several times a day with hot water. The patients learn easily how to take the appliance out and how to reinsert it. It is necessary to introduce the appliance immediately after the operation and to have it worn constantly, because otherwise the tissue retracts and then an anesthetic must be used in order to introduce the appliance. For the same reason a duplicate of the appliance must be made for use in case of repairs. Of the fifteen cases thirteen were resections of one-half of the lower jaw; one case was a resection of the middle part, and another case was a total resection of the lower jaw. This case was of special interest. Because of a sarcoma the whole lower jaw was removed in two operations. In this instance the immediate prosthesis had a middle piece which was inserted after the introduction of the side pieces. The functional and cosmetic results were remarkable.

A case of heart suture was demonstrated by H. Finsterer. The patient shot himself in the region of the heart in an attempt at suicide. The projectile penetrated the heart. The cardiac dullness was not increased, but over the heart there were heard abnormal sounds. By means of roentgenoscopy one could see the projectile lying in the heart and sharing in all its movements. After a few seconds it was caught in a whirl and thrown around. The heart was exposed and the punctured wound in the left ventricle near the auricle was sewed up. The removal of the projectile was not attempted because this procedure was too dangerous. In the pericardium little blood was found. The course of healing was uninterrupted. The patient has a pulse that is full and strong and then becomes scarcely perceptible. At the apex of the heart there is a systolic murmur. At the aortic area there is a diastolic murmur.

1. Education of the Public in Medical Matters.—H. D. Arnold states that a most excellent system has been developed in Boston for extending the instruction in health topics beyond the limits of the schools. In each district there is formed a home and school association composed of the teachers and such parents as are willing to join. Monthly meetings are held, and through lectures and discussions the effort is made to teach the parents what their children are learning at school in these subjects. From the school point of view this is very useful because it secures the cooperation of the home in teaching the pupils right methods of living. For the community it offers a most desirable means of educating the public.

6. Significance of the Absence of Trypsin in the Stomach in the Presence of Icterus.—A. E. Austin notes that many years ago Pawlow discovered that when oil is poured into the stomachs of his gastrostomized dogs, in one to two hours there began to flow from the fistula an emulsion which contained pancreatic juice and bile, in other words, duodenal contents which made its way back into the stomach through a relaxed pylorus. Boldyrew and later Volhard seized upon this physiological phenemenon to establish a clinical method of determining by the presence or absence of trypsin whether the functions of the pancreas are normal, impaired, or lost. It was found that individuals with normal digestion almost invariably show trypsin in their gastric contents 45 minutes after oil is taken. The author investigated this subject in ten cases representing the extremes of so-called malignant jaundice where cancer was the cause of the obstruction. By comparison of the mildest with the most severe cases one may learn that however valuable the absence of trypsin may be in the absence of jaundice, nevertheless when jaundice is present it seems to fail in the determination of the integrity of the pancreas. In none of the milder cases had there ever been an instantaneous access of pain such as is common where the jaundice is due to the sudden occlusion of the communis by stone, so that the theory of coincident closure of the choledochus and the duct of Wirsung by swelling of the mucous membrane of their several outlets is most probably in acute cases of short duration. The absence of trypsin in the presence of icterus may mean conjoint cholangitis and pancreatis, cholangitis with mere pressure on the outlet of the pancreatic duct, pressure of the enlarged head of the pancreas on the common duct, or mere pressure of a growth originating in the ducts on the pylorus. When in conjunction with this fact, one finds considerable residue in the fasting stomach, it is safe to conclude that there is pyloric narrowing due probably to outside pressure, and when the rare instance of bile without trypsin is found the inference to be drawn is that pancreatitis is primary and icterus secondary, due to pressure on the choledochus.

1. The Treatment of Obesity.—J. M. Anders is of the opinion that the majority of cases of this condition are to be attributed to a relative excess of food and a small expenditure of energy. A division of the cases into plethoric and anemic, as well as into general and local, should be attempted in practice. The anemic form often results from periods of enforced rest, e.g., after accidents, surgical procedures, and the acute infections such as articular rheumatism and typhoid fever. During middle life a tendency toward corpulency is frequently observed, when prophylaxis must have reference to the causative factors presented by individual cases. The treatment of confirmed obesity should be carried out under strict surveillance in all cases, and may be conveniently considered under three heads: (1) The dietetic treat-

ment; (2) the mechanical management, and (3) the medical measures. The author allows a limited proportion both of carbohydrates and fat, and thus accomplishes two objects, namely, a slow consumption of the previous fat deposits and maintenance of the normal metabolic processes. The carbohydrates are not to be withdrawn in toto, since the use of large amounts of proteins which are difficult of complete metamorphosis tends to excite gouty manifestations and digestive disorders and to inhibit favorable progress, or indeed to induce fresh complications that should be avoided. Muscular exercise for the purpose of accelerating oxidation is only slightly less important than an appropriate diet; it promotes destruction of the fat already warehoused in the system and invigorates both the circulation and respiration. Certain spas, especially Marienbad and Carlsbad, are effective in the plethoric, but not in the anemic type of obesity. Thyroid feeding has gained considerable professional favor. It may be employed in the anemic variety, more particularly if a myxedematous condition is present. The commencing dose should be small (one grain), to be slowly and gradually increased, but it is unwise to exceed three grains thrice daily.

2. Emetine in Dysentery.—J. Friedenwald and L. J. Rosenthal conclude that emetine is a specific in the treatment of amebic dysentery. It is quickly absorbed and its effect is rapid and striking. It produces no unfavorable symptoms such as nausea, vomiting, and depression. Other forms of dysentery are not favorably influenced by this remedy, so that its employment as a diagnostic measure is of the greatest value. Recurrences after apparent cure are not infrequent. It is therefore best to treat all cases showing a tendency to relapse intermittently with emetine.

4. Cardiac Hypochondriacs.—R. H. Babcock states that there is a not inconsiderable class of impressionable individuals who seek medical aid for a fancied disease of the heart. They suffer more from their subjective symptoms of palpitation, precordial pain, etc., than does many a patient with veritable organic heart disease. They are hypochondriacs because they fix their attention on their bodily sensations with such tenacity that these dominate their thoughts almost to the point of an obsession. It is found that however neurotic or impressionable the cardiac hypochondriac may be, the foundation of this fear is laid not in the primary attack of palpitation or precordial pain per se, but in the behavior of the physician or friend who suggested the likelihood of a serious heart disorder. It should not be inferred that the cardiac hypochondriac imagines his symptoms. He only exaggerates their importance and by his apprehension or actual fear intensifies their severity. This is true in particular of an attack of palpitation or intermittence. There are some features of the attack which should enable one to interpret its real nature. The sufferer is quite likely to be a young adult and more often than not a female, and in them grave angina is not so apt to occur as in a middle aged or elderly man. In most instances the individual is found lying in bed or perhaps groaning with pain instead of sitting or standing, as is the rule with cases of organic angina pectoris. There may be a history of previous attacks or the attack may be the first, and for this reason all the more terrifying to the patient and family. Furthermore, it is learned upon inquiry that between the seizures, provided others have occurred, or previous to the one observed if it happens to be the first, the individual has been free from symptoms referable to cardiac incompetence. Moreover, a true anginal seizure rarely occurs at night or when the person is quiet in the house or bed, without a history of pain in the chest upon exertion as on walking.

4. Gastric Residuum.—M. E. Rehfuss, O. Bergeim, and P. B. Hawks conclude that the accepted limit of the normal residuum of the empty stomach as 20 c.c. is false. The examination by means of the old stomach-tube as demonstrated by Harmer and Dodd and their own experiments is entirely inadequate. The method of examination by means of the new modified stomach-tube is the only satisfactory method of determining the complete residuum. On a series of healthy medical students the residuum in every instance exceeded the accepted limit and in several instances was above 100 c.c. without there being any evidence of gastrointestinal or general disorders. The significance of this symptom in relation to the diagnosis of ulcer must be seriously questioned.

5. Chronic Ocular Tuberculosis.—F. H. Verhoeff believes that in chronic ocular tuberculosis the infection of the ocular tissues takes place from the aqueous humor. The bacilli reach the latter from the blood through the ciliary processes, and are then carried to the filtration angle, whence they may pass into the cornea or sclera. They may also be deposited on the ciliary body or carried into the iris, producing focal lesions here, or into the subchoroidal space where they may give rise to choroidal foci. There is something special about this type of tuberculosis in addition to the mode or origin of the eye lesions. This is indicated among other facts by the following: Chronic ocular tuberculosis almost never occurs in cases in which there are well-marked clinical signs of systemic tuberculosis and in which, therefore, metastases would presumably be most apt to occur. On the contrary, it occurs chiefly in cases in which it is difficult or even impossible to find any other indications of tuberculosis. Although chronic ocular tuberculosis is rare compared to the incidence of tuberculosis in general, yet when it occurs it is almost always sooner or later bilateral, thus showing plainly that it does not represent chance metastases. It occurs almost exclusively in adults and sometimes even in patients of advanced age. It occurs far more frequently in females than in males. The temperature is almost never elevated and is often subnormal. A large dose of tuberculin is usually required to produce a constitutional reaction, and rarely a tuberculin reaction cannot be obtained at all. Acid-fast tubercle bacilli seldom if ever can be demonstrated in the lesions. Animal inoculations of the lesions usually if not always give negative results.

7. Ocular Manifestations of the Toxemia of Pregnancy.—W. A. Holden reports the case of a patient who was about seven months pregnant, for the second

time, and who had vomited the first three months of her pregnancy, and whose feet had been swollen at night. Her chief complaints, however, were that for five days she had seen double, and that during this time the sight of each eye had grown rapidly worse. Examination of the eyes showed a paresis of the left external rectus and an absolute central scotoma in the field of each eye so extensive that vision was reduced to the recognition of movements of the hand, but this was possible in the entire periphery of each field. The fundi were normal in appearance except for a trace of retinal edema about the macula lutea in each eye, which was not sufficiently marked to cause obscuration of vision. The author advised the immediate induction of labor in order to save her vision, and the patient was at once delivered of an eight-months' stillborn child. From an obstetrical point of view she had a rapid and uncomplicated recovery, and her sight became rapidly better, while the albumin was reduced and the blood-pressure fell, and she was discharged in good condition. This curious chronic progressive disturbance in the pigment epithelium the retina would seem to be due to the same toxic condition of the blood which, when more intense, caused paresis of one external rectus muscle and the retrobulbar affection of the optic nerves. The night blindness of scurvy, for example, must be attributed similarly to the action of the altered blood on the pigment epithelium. The characteristic lesion in eclampsia is a more or less localized edema of the intracranial tissues, of sudden onset. Complete transitory blindness with normal fundi is a fairly frequent symptom of eclampsia. In many of the cases of blindness in eclampsia one must suppose that there is an edema affecting the calcarine cortex or the optic radiation on each side, which in some cases causes destruction of tissues and therefore produces permanent defects in the fields of vision.

10. Chestnut Blight and Chestnut Toxemia.—C. D. Marsh states that an examination of the reported cases of poisoning from eating chestnuts collected from trees affected with the chestnut blight showed that there was no evidence that nuts from blighted trees contain any more deleterious properties than those from healthy trees, and the symptoms which had been supposed to be connected with blighted chestnuts could in almost all cases be explained as symptoms which would be produced by healthy chestnuts in some persons. Laboratory experiments in feeding the whole fruit, in the use of extracts, and in chemical examinations failed to show any toxic properties in the nuts.

7. A Case of Gallstone Causing Intestinal Obstruction. S. Wickenden.

1. Hygienic Aspects of Coalmining.—F. Shufflebotham states that anthracosis must be regarded in coal miners at the present time, not as a pathological condition, but simply as one physiological in nature. Coal dust is not an irritant to the lung tissue, and the microscopical examination of sections taken from anthracotic lungs bears testimony to this opinion. Tuberculosis of the lungs is not so commonly found in coal miners as in many other occupations. It has been asserted by many authorities that coal dust has germicidal properties, and in favor of this view there is the experience of colliery surgeons who record that extensive wounds full of coal dust heal rapidly, and even lacerated wounds sustained through injuries in coal mines can be stitched up without hesitation. The mortality from lung diseases among the Cornish miners has been known to be very high for many years past. Exposure to dust from working machine drills predisposes not only to lung trouble but also to an early death. The miners' phthisis found in Cornwall is caused by the silica-laden atmosphere of the mine; the symptoms and course of the disease are exactly the same as those of potters' asthma or stone masons' phthisis. Tuberculosis is as comparatively rare among the South African miners as it is among the coal miners of England. In a considerable number of mines in England the men are working at very high temperatures, and these temperatures not only are injurious to the health of the worker, but have a considerable effect upon their working capacity.

2. Treatment of Leprosy by Intravenous Injections of Iodoform.—B. J. Courtney notes that recently W. M. Crofton reported his method of treatment of pulmonary tuberculosis by means of intravenous injections of tuberculin and iodoform, which in his hands had met with considerable success, and it occurred to the author that this treatment or some modification of it might be worth trying in leprosy, a disease which in many respects, both clinical and pathological, bears resemblances to tuberculosis. Of the 12 patients on whom the treatment was tried for three months or longer, 4 were of the purely nodular type, 5 were of the purely anesthetic type, and 3 were of the mixed type. As regards the duration of the disease at the time treatment was commenced, the shortest was two years and the longest was seventeen years. One-half grain of iodoform was given twice a week; this was gradually increased up to one grain given five times a week. In addition to the intravenous injections, in four cases a local reaction was aimed at also: the solution of iodoform was injected into the substance of the nodules, the amount varying from 10-30 minims of the solution according to the size of the nodule. Four or five nodules were treated in this way at the same time, and when the resulting ulceration had healed another four or five were injected, and so on. Of the tubercular cases four were treated, three of which showed marked improvement during the period, and two of the mixed cases also showed improvement as regards the tubercular portion of the disease. As regards the effects on special symptoms and on the general health, it is noted that all the patients treated, both tubercular and anesthetic, said that they felt better and stronger as a result of the treatment, that their appetites had improved, and that they were able to do more work.

6. Acute Non-Calculous Cholecystitis in a Child.—F. C. Pybus reports a case of this condition in a boy aged six years, who was admitted to the hospital with a diagnosis of appendicitis. The history was that the child had a bilious attack and vomited a good deal. The vomiting was repeated for three days, during which time there was no constipation or abdominal pain. The boy then appeared fairly well for two days. On the day before admission he was again vomiting and had severe abdominal pain on the right side. On admission the child looked ill, had a temperature of 101° F. and pulse 132. He looked pale and was sweating. The pain was over the upper part of the right rectus. On abdominal examination some distention was noticed in the upper abdomen on the right side.

There were rigidity and tenderness over the upper part of the right rectus. The right iliac fossa was slightly tender but not rigid. The remainder of the abdomen was flaccid and not tender. On more careful examination a definite mass could be felt under the right rectus, and this part was dull on percussion. An operation was performed at once, revealing an enlarged and inflamed gall-bladder. This was about the size of a hen's egg, and was tense and green in color, the vessels being injected. An exploring syringe drew off some bile-stained pus. The symptoms and signs of acute cholecystitis in children very closely resemble those occurring in the adult. Khantz, in a paper quoted by Moynihan, states that he has found in the literature a record of only five cases of non-calculous cholecystitis in children. Three of these were secondary to scarlet fever, enteric fever, and appendicitis. Cholecystectomy was performed on four patients, and in three instances with success.

1. The Adrenal Glands. T. R. Elliott.
2. Some Clinical Aspects of the Body Temperature in Childhood. T. R. C. Whipham.
3. The Vicious Circles of Neurasthenia. J. B. Hurry.
4. Internal Secretions and Dental Caries, with Special Reference to Thyroid Insufficiency. H. P. Pickerill.

1. The Suprarenal Gland.—T. R. Elliott states that the suprarenal gland is a twofold structure. Its center is composed of masses of delicate semi-fluid cells, which are richly supplied with sympathetic nerves and lie enmeshed among thin-walled veins. These contain suprarenal extract. Intermingled here and there with them and growing out over the surface of the cells supplying the internal secretion, so as to form a complete envelope to the medulla, are the cells of the cortex. Their innervation is scanty and they yield no known active principle, but they are generally laden with a rich store of a peculiar fatty substance. It has been proved that the medullary cells deliver the suprarenal extract directly into the venous blood stream, and that they do this in part automatically, but chiefly in response to a call made through nervous impulses descending by the splanchnic nerves. Removal of the suprarenal glands, that is, of cortex as well as of medulla, brings death. Physiology has a tolerable full knowledge of the nature of the medullary cells of the suprarenal glands. Pathology merely confirms this. In many diseases the content of the glands in the internal secretion is diminished, but not often to what might be looked upon as a really serious state of depletion. The chief activity of the cortical cells is directly towards the formation of this special fatty substance. It is particularly abundant in the glands of man, and some quite definite knowledge with regard to it has been accumulated by several pathologists who have studied the adrenals in death from various diseases. Inanition from cancer of the alimentary canal or the beggarly emaciation of anorexia nervosa strip all the fat from the body and yet the cortex has its customary load. On the other hand, the cortical fat vanishes in a couple of days' acute fever, by which the depots of the body fat are hardly touched. All septic fevers reduce the cortical fat rapidly. The most obvious example of this is in acute pneumonia, in which the gland becomes fatless, edematous, and swollen to twice its natural size. Slow febrile processes, such as that of chronic tuberculosis, cause much less exhaustion. But the removal of the lipoid is not determined simply by a physical change in relation to the rise of temperature. Its increase is also manifest in some diseased states. Single large adenomatous masses of cortical cells that are packed with lipoid may occur in any individual and irrespective of any particular illness. But in kidney disease of the arteriosclerotic form, where the atheromatous change is widely spread through the vessels of the body, the cortex does tend to proliferate in numerous small adenomata or even to show a general massive hypertrophy. These pathological facts therefore make it reasonable to regard the cortex with respect to its fat-holding function as a tissue altogether apart from the medulla and the sympathetic nervous system. The cortical cells seem to be essential for the maintenance of life. The cortical cells are also of importance in the development of man's body during the early period of life, especially with respect to his brain and sexual attributes. Paleness appears early and with exaggerated emphasis in children whose suprarenal glands are the seat of proliferative tumors. The morphological evidence is sufficiently weighty to determine the balance in favor of the view that the cortex primarily controls nutritive material in regard to growth and reproduction.

2. Clinical Aspects of the Body Temperature in Childhood.—T. R. C. Whipham states that the vagaries of the body temperature in childhood are frequently perplexing and difficult to understand. In early life the temperature is very variable and uncertain; it may show marked oscillations from slight or trivial causes or rise to a considerable height for no apparent reason. On the other hand, a child may be seriously ill, perhaps with bronchitis or empyema, and the temperature chart will record but little variation from the normal. The heat regulating centers in childhood, as is the nervous system as a whole, are generally in an unstable condition, and may be influenced by emotional or slight physical causes, or they may fail to respond in the way one should naturally expect to a stimulus sufficient to cause a definite amount of fever in the adult. Undue stress, therefore, must not be placed upon the temperature of children. A transitory rise, even though it may be to 102 or 103°, need not necessarily cause alarm, although, of course, one should at all times seek for some underlying cause, especially if the elevation happens to be repeated. In this connection it is as well to bear in mind that in infants when once the heat center has been disturbed, some time may elapse before it regains its equilibrium, and that slight variations in the temperature may persist for a while after the exciting cause has been removed. On the other hand, a temperature which adheres more or less closely to the normal must not lead one to make light of any other physical signs which the child presents.

3. The Vicious Circles of Neurasthenia.—J. B. Hurry points out that a disorder of the ideational life is a striking feature of neurasthenia. This often leads to the genesis of anxieties and phobias, which prolong the state of exhaustion of the neurons. Mental depression is another common symptom of neurasthenia and aggravates the condition. A complex circle may be established when the perverted ideation leads to loss of appetite, refusal of food, and consequent emaciation. Insomnia is another psychogenous symptom of neurasthenia which often greatly impedes recovery; the associated cerebral hyperemia prevents the neurons from obtaining the rest on which their recuperation so greatly depends. Neurasthenic persons are frequently obsessed with the fear of heart disease and the consequent worry intensifies the neurasthenia. The sequence of events is somewhat as follows: The fear of organic heart disease leads to autosuggested sensations in the cardiac region, followed by a disturbance

of the cardiac action, such as tachycardia, occasional extra-systoles with palpitation, and an intermittent pulse. The associated sensations then arouse distress and terror, which in their turn further disturb the cardiac activity. Such attacks are especially common at night and may be caused by nightmare, and the operation of this circle may reduce the neurasthenic person to a condition of utter prostration or even lead to fatal syncope. Probably the digestive system is more often affected by vicious circles than any other system, owing to the peculiarly intimate relation between the central nervous system and the viscera. In a neuropathic person almost any painful disorder is liable to increase the neurosis. Treatment of neurasthenia resolves itself into breaking the vicious circles that complicate the disorder. Hence the importance of the physician being familiar in detail with the various factors which perpetuate the morbid gyrations. He should prepare his plan of campaign. He should seek the *locus minoris resistentiæ* and direct his broadside so as to effect a breach at the weakest spot. In functional disorder the treatment of symptoms may in itself be of great importance. Psychical disorders will create and psychical treatment will often break a vicious circle. Although psychotherapy may bring instant relief the primary disorder is as a rule not permanently cured. The chronic exhaustion of the neurons remains, with an abiding tendency to relapse on provocation. Carefully devised constitutional treatment is here called for, therapeutic measures being carefully adapted to each case. Rest, work, isolation, supernutrition, and change of air and environment, may each and all prove efficient in suitable cases.

4. **Internal Secretions and Dental Caries.**—H. P. Pickerill concludes that there is some reason to think that deficiencies of the thyroid and perhaps of the pituitary and thymus secretions are concerned in the lowering of the resistance of the teeth to caries. Because thyroid insufficiency may be a causative factor in certain patients, one should not conclude *ipso facto* that it is always a cause of caries. There are very many other factors, physiological and pathological, which must also always be taken into consideration.

June 22, 1914.

Investigations into Icterus.—Hymans van d. Bergh and Snapper sum up their serial account of this infection as follows: They have made certain observations and experiments, and have adhered throughout to facts to the neglect of theories. Their work on the ancient question as to whether coloring matter is normally produced in the liver alone, or in the liver and other organs, has led to nothing of value. McNee's surmise that bilirubin is formed in certain elements of the liver (perhaps in Kupfer's star-shaped cells), but excreted into the bile capillaries by the essential cells of the liver, seems fertile. As soon as blood leaves the vascular paths and is poured into the tissues we see a local formation of biliary coloring matter, which in turn is absorbed into the circulation. If the bilirubin content of the blood attains a certain concentration, the liver cells excrete the coloring matter into the bile passages. A certain portion of the bilirubin, however, is held back in the blood stream and is not eliminated by the hepatic cells. This quota differs with the species of animals. The majority contain but little, the dog almost none at all. Certain animals contain a good deal—mankind, and especially the horse. There are also notable fluctuations in individuals, which, however, are insufficient to disturb the physiological equilibrium. If the function of the liver cells is damaged—for example, in stagnation, as a result of myocardial insufficiency—then the formation of bilirubin is curtailed, while the content of this substance in the blood-serum is correspondingly increased; the same result occurs when bile is excreted in excess. In gross mechanical obstruction the bilirubin in the blood serum reaches a concentration at which the kidneys begin to excrete it. If the causes persist, the skin becomes jaundiced. These ideas of bile secretion correspond to the modern idea of the excretion by the kidney of salt and sugar; in each the vital point is the blood-concentration of the various substances.

Excretion of Typhus Bacilli in Carriers.—Hirschbruch has studied the action of various substances on the typhoid bacilli in the intestines of carriers. He regards the use of calomel as of doubtful value as a prophylactic in those as yet not infected. In some carriers aloes with podophyllin brings away the bacilli. One carrier with chronic diarrhea, in whom over 50 negative tests of the stools were made, gave a positive result after a castor oil movement. Naturally some bacteria may escape through the kidneys. In the expulsion of the same by the intestine something irritant should be indicated—aloes or podophyllin, or even croton oil. The authors' material is grouped as follows, due allowance being made for the periodical pauses between excretions, and for the great number of negative tests in general. Purgatives often make positive tests possible. Here castor oil, or sesamol with a little croton oil, aloes, podophyllin, have been used with success. In this class the patients naturally show no periodicity. If the excretion is regular, calomel is used with profit.

Münchener medizinische Wochenschrift.

Disturbances of the Internal Secretions in Chlorosis.—Schmitt states that the primitive theory of the hemic origin of this affection has undergone much revision. There have been gradually associated with chlorosis certain lesions which point to other causal elements, such as organic heart disease and functional disturbances of the uterine mucosa. In fact, chlorosis is now believed to involve the entire organism, and to be in fact a basic anomaly of the latter. This in turn almost necessarily implies a disturbance of the organs of internal secretion. It should have been stated that chlorosis may exist clinically with complete absence of the chlorotic blood picture. The author, proceeding upon the temporary belief that the disease is bound up in a disfunction of the uterus and ovaries, has made use of Abderhalden's procedure in the solution of the problem. Typical cases were selected by the following complex: high degree of pallor, puffiness of the skin, disturbances of function of the heart and vessels and of the genitals. No blood picture is mentioned. Controls were used. Of two severe chlorotics tested, one reacted negatively to liver, spleen, thyroid, and adrenal, but positively to ovarian tissue and to uterine tissue. The other chlorotic reacted negatively to liver, pancreas, spleen, and ovary; but positively to uterine tissue. Fifteen other chlorotics of a relatively mild type gave three positive results to human ovary and seven positives to animal ovary. To human uterus there were seven positive reactions, and to animal uterus, eight. There were some negative results, but not nearly enough to outweigh the positives. In a small number of cases the four tests were not all made, the test with human organs being occasionally omitted. Other organs, as a rule, gave solid negative results, but there were two positives with the spleen and one with thyroid.

Insurance Medicine.

THE WORK OF THE MEDICAL EXAMINER.*

By HENRY WIREMAN COOK, M.D.,

MINNEAPOLIS, MINNESOTA.

MEDICAL DIRECTOR NORTHWESTERN NATIONAL LIFE INSURANCE COMPANY.

It gives me great pleasure to open this fourteenth meeting of the American Association of Medical Examiners. I believe the program will be both interesting and instructive and that the meeting will indicate the progress that medical examiners for life insurance are steadily making towards a better appreciation and understanding of this specialty of our profession.

I ask your attention for a few minutes to a brief consideration of the purposes of this organization and its need in giving the dignity, the scientific basis, and the professional standing to this specialty which it demands, and which is exemplified individually in the large number of physicians who are now deriving all or a goodly portion of their income from this work. For the layman or physician who thinks that the ordinary medical course or the experience of medical practice is all that is necessary in order to do efficient work as a medical examiner, the experience of the medical officers of all insurance companies would afford much of interest and astonishment.

The examination of a patient by a physician and of an applicant by an examiner offers many different and some entirely opposite considerations. A good diagnostician and physician frequently makes a very poor expert witness on the stand, and similarly many excellent physicians, either through inexperience or through ignorance, lead their companies to assume extra hazardous risks at inadequate rates.

To make an accurate diagnosis in a patient under the prolonged and detailed methods of good clinical practice, and to exclude or accurately gauge an impairment and every impairment in an applicant for insurance, are two very different problems, and the training and experience which might well suffice in the first instance might and does frequently in practice fail in the second. The patient comes to his medical attendant desiring that his ailment be thoroughly understood and well defined, and he lends every aid by history, symptoms, etc., submitting himself to the necesary, sometimes painful, clinical methods.

The applicant for insurance regards the examination as an inconvenience, and with more or less dread and antagonism, realizing that it may, through what he may regard as a technicality, deprive his wife and children of financial protection or himself of business credit. He will, therefore, particularly if he knows or suspects that he is impaired, naturally not assist, but will rather attempt to thwart, the examiner in his work. Some applicants will undergo dietary treatment, some resort to drugs, in order to pass the examination. A few days' rest in bed and a milk diet have cost companies many thousands of dollars, and nowadays a grain of sodium nitrate will often deceive even the sphygmomanometer.

In addition to the problems of the examination itself there are many conditions and much statistical information which must be intelligently correlated in insurance work, and which are only vaguely, if at all, appreciated by the average practitioner. Insurable interest, moral hazard, occupation hazard, for example, are vital in insurance work, but only indefinitely recognized in general medicine.

The significance of a trace of albumin in apparently healthy men is distinctly an insurance problem, for the practice of routine examinations of healthy persons by their medical attendants has not yet become sufficiently common to afford the general practitioner the necessary data or experience.

All business is developing, and must develop if it would persist, along the lines of increasing economy and efficiency. The hit-or-miss methods of the past generation will not pass muster today. To this economic demand insurance offers no exception. Extravagant salaries, the wasteful or criminal manipulation of trust funds, speculative investments, are not to be found in American insurance companies today. Medical selection shares in the general uplift, and must meet the demands of higher standards. Mortality savings are appreciated by the policyholder or stockholder when returned in increased dividends. The time is past when the medical director is overruled because the applicant is influential or is a director or stockholder of the company. The companies realize that the basis of their medical selection must be the work of the medical examiners, and they are continually reviewing their lists, weeding out the incompetent, and substituting better trained men.

This association is a recognition by its members of their interest in life insurance examining and their ambition to study the requirements of the work as well as to improve their individual practice of it.

I believe that the interests of our specialty, as well as of our general profession, would be best conserved by the union between our association and the American Medical Association. General medicine already owes much to insurance medicine, particularly, of course, in prognosis, but also much in diagnosis and prophylaxis. No statistical records available on mortality and varying medical requirements can compare to that offered in such investigations as the medico-actuarial investigation. Much of the medical knowledge and best training of many general practitioners is gained through their insurance connection. For example, competent uranalysis and blood pressure estimation have been largely instilled in the rank and file of the profession by the educational work and the routine demands of insurance companies. As another example of this debt of general medicine to insurance medicine we should note that the present acceptance of periodic physical examination by laymen is largely due to the insistence of insurance officials, medical and lay. Such an amalgamation does not seem practical at this time, and in the meanwhile our association should make valuable contribution to our knowledge and literature of the subject.

We have received signal encouragement from the medical officers of a majority of the companies, and will continue to receive their advice and assistance. I cannot too strongly urge all physicians interested in the work of insurance examining to join the association, and by their influence and experience to assist in developing better work and a higher standard of excellence.

*President's Address at the Annual Meeting of the American Association of Medical Examiners, Atlantic City, N. J., June 22, 1914.

Book Reviews.

LECTURES ON DIETETICS. By MAX EINHORN, Professor of Medicine at the New York Postgraduate Medical School and Hospital and Visiting Physician to the German Hospital, New York. Price $1.00 net. New York: Paul B. Hoeber, 1914.

THIS little volume on dietetics comprises a series of lectures on the subject given by Dr. Max Einhorn at the New York Postgraduate Medical School. Diet in disease is mainly dealt with and statements on this point from an authority such as is Dr. Einhorn must carry weight and cannot fail to be of value to the busy practitioner.

THE ROAD TO A HEALTHY OLD AGE, Essays Lay and Medical. By THOMAS BODLEY SCOTT. Price $1.00 net. New York: Paul B. Hoeber, 1914.

THIS little work comprises a selection of lay and medical essays, and from the literary and scientific point is eminently satisfactory. The author gives useful hints as how to best ward off old age and does this in excellent language and style. The latter part of the book is devoted to a consideration of vaccine therapy and appears to be a thoroughly clear description of the theory and practice of this most modern phase of medicine. The volume is instructive and interesting.

DIE PRAKTISCHE BEDEUTUNG DER MISSBILDUNGEN DER NIERE, DES NIERENBECKENS, UND DES HARNLEITERS. Von Prof. Dr. C. ADRIAN. Price 1.20 Mks. Halle a. S.: Carl Marhold, 1914.

PROF. ADRIAN reports the results of a varied and rich experience in his clinic in malformations of the kidneys, of the pelvis, of the kidney, and the ureter, which will interest that circle of physicians who are not urologists as well as the specialists in that branch.

ENTSTEHUNG UND ENTWICKELUNG DER LARYNGOSKOPIE. Von Prof. Dr. EMERICH VON NAVRATIL. Price 1.60 Mks. Berlin: August Hirschwald, 1914.

GEHEIMRAT VON NAVRATIL gives some interesting case histories and an account of his treatment of them, gathered from the experience of a long practice in laryngoscopy (1858-1913).

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia; assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price $6.00 per annum. Philadelphia and New York: Lea & Febiger, March 1, 1914.

THIS number of "Progressive Medicine" contains a new section on surgery of the thorax, excluding diseases of the breast, by G. P. Müller. Otherwise the volume is similar to the corresponding number in former years. The section on surgery of the head and neck is contributed by C. H. Frazier; that on infectious diseases, including acute rheumatism, croupous pneumonia, and influenza, by J. Rührah; diseases of children by F. M. Crandall; rhinology and laryngology by G. B. Wood, and otology by A. B. Duel. There can be no possible doubt as to the value of the publication to the practising physician.

DIE ZUCKERKRANKHEIT (DIABETES MELLITUS), IHRE URSACHEN, WESEN UND BEKÄMPFUNG. Von Dr. med. A. SOPP. Price, 1.50 Mk. Würzburg. Curt Kabitzsch, 1914.

DR. SOPP in the second edition of his pamphlet on diabetes, relates the progress made in its treatment. He gives a table with the quantity of the different foods which contains 70 gr. of carbohydrates and he discusses the use of vegetarian diet.

GEBÜRTENRÜCKGANG UND MÄNNLICHE SEXUELLE IMPOTENZ. Von Dr. P. LISSMANN. Price, 1.20 Mk. Würzburg: Kurt Kabitzsch, 1914.

THE writer states that the fall in the German birth rate only affects the married element, as the illegitimate rate is increasing. He attributes the fall to neomalthusianism, suffrage, the share of women in industrial life, sexual perversities of the husband, too long abstinence, and adds that 80-90 per cent. of the abortions handled in the Berlin University Policlinic are criminal.

MILITÄRÄZTHICHE KRIEGSERINNERUNGEN AN 1866 UND 1870-71. Von Dr. M. PELTZER, Generaloborarzt a. D. Price, 1 Mk. Berlin: August Hirschwald, 1914.

SURGEON-GENERAL Peltzer recounts a number of most interesting reminiscences of the part the German surgeons took in the campaign of 1866 and that of 1870-71.

DIE MODERNE THERAPIE DER GONORRHÖE BEIM MANNE. Von. Prof. Dr. PAUL ASCH. Price, 3.20 Mk. Bonn: A. Marcus & E. Weber, 1914.

PROF. Asch gives twelve lectures on those methods of treatment of acute and chronic gonorrhœa and their complications which have had the best results in his fifteen years' practice as specialist. He lays particular stress on the great value of a urethroscopic examination following a vaccine injection prior to the permission to marry for gonorrhœa convalescents.

BEHANDLUNG KOSMETISCHER HAUTLEIDEN. Von Dr. S. JENNER. Price, 2.50 Mk. Würzburg: Curt Kabitzsch, 1914.

THIS is the third edition of Dr. S. Jenner's lecture for practitioners on the treatment of cosmetic defects. It is written so admirably, however, that it will be appreciated by the layman, or rather by his wife.

DER AUSFALL DES KOPFHAARS UND SEINE BEHANDLUNG. Von Dr. FELIX PINKUS. Price, 1.60 Mk. Halle a. S.: Carl Marhold, 1914.

THERE are several interesting pages in this little pamphlet on the neurotic and inner secretory forms of alopecia areata, based on recent research in the ductless glands. The usual combination of theory and formulæ of the Jadassohn dermatological series is followed in this dissertation.

DIE STÖRUNGEN DES VERDAUUNGSAPPARATES ALS URSACHE UND FOLGE ANDERER ERKRANKUNGEN. (III Part.) Von Dr. HANS HERZ. Price, 9 Mks. Berlin: S. Karger, 1914.

THE book of this well known author has now appeared in its second edition. In reference to the disturbances of digestion in tuberculous patients the author says: "It is an undoubted fact that digestive troubles bring many tubercular patients to the physician who through anamnesis or examination discovers an old or recent lung affection or suspects only a beginning phthisis. The early and marked occurrence of such symptoms may be explained in two ways. On the one hand the bacilli may in some cases be particularly numerous and virulent and finding their way early to the digestive tract, form poisons deleterious to stomach and bowel. On the other hand the condition of the digestive apparatus at the time of infection is a disposing factor not to be overlooked."

"There is furthermore, no doubt that symptoms of intoxication without marked tissue changes can arise from tuberculous foci just as in other infectious diseases. The toxins reach the various organs by the blood and in the case of the digestive tract possibly also by the sputum. They act directly on the parenchyma and its nervous apparatus, also indirectly through local or higher nerve centers. To this may be attributed the initial dyspepsia of tuberculous patients. To prove clinically that digestive disturbances are the result of tuberculosis is mostly very difficult, even in such affections of the mouth, pharynx, or rectum that are readily accessible to inspection, much more so in deep-seated affections. Since these disturbances are the expression of a general affection, we will expect to find the characteristic premonitory signs: heredity, phthisical habitus, tubercular affection of other organs, temperature variations, hyperhidrosis, lack of nutrition reactions to specific products of tubercle bacilli and serological differences."

The author then discusses the disturbances of digestion in other chronic infectious diseases, viz., leprosy, actinomycosis, rhinoscleroma, and syphilis.

THE ANATOMISTS' NOTEBOOK. A Guide to the Dissection of the Human Body. By A. MELVILLE PATERSON, M.D., Edin., F.R.C.S., Eng. Price, $2.00 London: Henry Frowde; New York: Oxford University Press, 1914.

THIS manual is intended essentially for use in the dissection room, and the author says it is to be supplemented by a knowledge of osteology and a systematic textbok. There are many illustrations and very clear directions.

Les Techniques Anatomo-Pathologiques du Système Nerveux; Anatomie Macroscopique et Histologique. Par Gustave Roussy et Jean L'Hermitte. Price, 5 francs. Paris: Masson et Cie., 1914.

Pierre Marie writes in his preface to this book that its place is not on the library shelf, but on the laboratory table beside the fixatives and staining fluids. The authors give the methods for the preparation of nervous centers, macroscopical sections, and selection of material for bistological research. They review the technic of fixation, inclusion and staining of the different parts of the nervous system. The methods have been all used for years by Prof. Roussy.

Deutsche Zahnheilkunde in Vorträgen. Heft 32. Innere Sekretion in Beziehung zur Kieferbildung und Zahn Entwoicklung. Von Dr. med. P. Kranz. Price, 2.80 Mk. Leipzig: Georg Thieme, 1914.

The writer explains the bearing of the recent researches on the effects of the internal secretions on jaw formation and on the development of the teeth. There are fifty excellent plates and a good bibliography.

Innere Sekretion. Ihre physiologischen Grundlagen und ihre Bedeutung für die Pathologie. Von Prof. Dr. Artur Biedl, Wien. Mit einem Vorwort von Hofrat Prof. Dr. R. Paltauf, Wien. Zweite, neubearbeitete Auflage. Zweiter Teil. Mit 56 Textfiguren und 13 mehrfarbige Abbildungen auf 6 Tafeln. Berlin: Urban & Schwarzenberg; New York: Rebman Company, 1913.

The second volume of the new edition of Biedl's encyclopedic monograph on the inner secretions completes the chapter on the suprarenal system and includes sections on the carotid and sacral glands, the hypophysis, the genital glands, and the internal secretions of the pancreas, of the stomach, of the mucous membranes of the intestine, and of the kidney. A bibliography of 256 pages, including papers published in 1913, is appended. It is impossible to include within the limits of this notice the important features of this standard book. While it does not attempt to be absolutely critical, yet the presentation of the views of various investigators quoted are given with fair fullness. In contrast to many German publications it gives credit to the important work of American investigators; for example, the studies of Cannon and his pupils on the emotional stimulation of adrenal secretion and on emotional glycosuria are fully reviewed. It is a satisfaction to note that the widely published erroneous statement that the so-called adrenal tumors contain adrenalin is finally corrected; while the tumors arising from the chromaffin medullary tissue, the so-called paragangliomata are shown to contain a substance which raises the blood pressure. A very good presentation is that of the chemistry of the adrenal glands apart from their specific secretion. A large amount of research has been done on the lipoid substances present in the adrenal, and yet it is difficult to find elsewhere a connected review. The hormone theory of mammary gland influence comes in for a good deal of discussion. The author rather holds to the views of Starling despite the published critique of Frank and Unger. Six very beautiful colored lithographs show the structure and relations of the hypophysis and various pancreatic lesions.

A Short Practice of Midwifery for Nurses, Embodying the Treatment Adopted in the Rotunda Hospital, Dublin. By Henry Jellett, B.A., M.D. (Dublin University), F.R.C.P.I. Master, Rotunda Hospital; Extern Examiner in Midwifery and Gynecology, Victoria University, Manchester; late King's Professor of Midwifery, University of Dublin, and Gynecologist to Sir P. Dun's Hospital; Formerly Gynecologist and Obstetrical Physician, Dr. Stevens' Hospital; Censor and Examiner in Midwifery, Royal College of Physicians, Ireland; University Examiner in Midwifery and Gynecology, Dublin University, Extern Examiner in Midwifery and Gynecology, Royal University of Ireland. Fourth Edition, revised: fourteenth thousand. With six plates and 169 illustrations in the text; also an appendix, a glossary of medical terms, and the regulations of the Central Midwives' Board. Price $2.50. New York: Paul B. Hoeber, 1914.

This is as good a book for nurses as we have ever seen; in many respects it might serve as a model for writers of books for nurses dealing with other subjects. The information given is accurate, and well selected: and there is no needless parade of unnecessary material. The author has proceeded on the assumption that a nurse should be able to manage every case of normal labor, and in other cases to send for medical assistance; at the same time she should be able to look after her patient pending the arrival of the physician; it is further assumed that the readers of this book aim at being good nurses and not bad doctors.

A Manual of Infantile Paralysis. With Modern Methods of Treatment, Including Reports Based on the Treatment of Three Thousand Cases. By Henry W. Frauenthal, A.C., M.D. Surgeon and Physician-in-chief, New York Hospital for Deformities and Joint Diseases and Jacolyn Van Vliet Manning, M.D. Epidemiologist, Wisconsin, 1908, Epidemic Acute Poliomyelitis. Copiously illustrated with more than one hundred engravings, nearly all original. Price $3.00 net. Philadelphia: F. A. Davis Company, 1914.

There is no other disease in which such rapid progress has been made in the study of its prevalence, dissemination, and etiology, as in the case of poliomyelitis. Within a few years there have been discovered the facts that this disease may be transmitted to animals, and that various insects, chiefly the stable fly, may carry the infection, and its parasitic cause, a protozoan probably akin to that causing rabies, has been isolated and cultivated. Within the past few years a number of works on infantile paralysis have appeared in the English language. These include translations of Wickmann's, Vulpius', and Romer's works, and of the contributions by Kling, Pettersson and Wernstedt. To these is now added the admirable volume by Frauenthal and Manning, which deals with every aspect of the disease, from the description of the protozoan parasite recently cultivated by Noguchi, to the method of treating some of the deformities by means of exercises performed before a mirror. The book is eminently practical. It contains a large number of excellent illustrations. There is a certain lack of proportion in the discussion of various phases of poliomyelitis. Thus, considerable attention is given to Manning's studies of an epidemic in Wisconsin and of the habits and possible rôle of the bedbug in carrying the disease, while only brief mention is made of the surgical treatment of poliomyelitis, a subject which has been greatly elaborated within recent years. A few errors have crept into the text. Thus, on page 22 mention is made of a "Gram positive diplococci" and on page 23 of "a media of nutrient broth." On the whole, however, the volume is well written and forms a valuable contribution to medical literature.

Die Therapie des praktischen Arztes. Herausgegeben von Prof. Dr. Eduard Müller, Direktor der medizinischen Univ.-Poliklinik in Marburg. Erster Band. Therapeutische Fortbildung, 1914. Mit 183 teilweise farbigen Abbildungen im text und auf 4 tafeln. Price, Vol. I, 10.50 Marks; Vol. II, 6.40 Marks. Berlin: Julius Springer, 1914.

These two volumes constitute a practical course in therapeutics for the general practitioner. Volume one consisting of 1056 pages summarizes the latest therapeutic progress up to the year 1914. The opening article is by Neisser and deals with the subject of venereal diseases and the medical examination requisite to the clean bill of health with reference to marriage. Some of the other articles are the treatment of tuberculosis of the skin, by Veiel; the treatment of eczema, by Zieler; the feeding of healthy and sick children by Vogt; the preparation of the infant's food, by Stolte; asthma and its treatment, by Breens; the treatment of obesity, by Hürter; obstetrical operations in the private house, by Zangemister; the surgical treatment of cholelithiasis, by Poppert; toothache and its treatment, by Fischer and Moral. These represent only a few of the large number of articles in which newer methods of treatment have been evolved within the past few years. They are succinctly written, and contain many details of practical value. The second volume of this work consists of 664 pages and some of its articles are as follows: the economic aspects of prescribing, by Sordeman; a list of proprietary drugs with their chemical equivalents; abbreviations; the prescribing of drugs according to indications; and useful remedies. The last article, which is written by Frey, consists of 171 pages and comprises a compact materia medica. There are also articles on the newer remedies, and secret remedies, so-called patent medicines, maximal doses, the symptoms and treatment of acute poisonings, incompatibles, drops, solubilities, saturations, the principles of serumtherapy, etc. This volume, like its companion, is compact and full of useful information.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held April 21, 1914.

DR. JOSEPH C. ROPER IN THE CHAIR.

Myotonia Atrophica.—Dr. J. G. BULLOWA presented this patient, a man thirty-eight years of age, single, and a storekeeper. He came under observation February 9, 1913, complaining of cramplike spasms, which had lasted for several years, and weakness of the left upper extremity. He had always been a large, heavy man, weighing 187 pounds. There was no similar disease in the family. Eighteen years ago he had been operated upon for left varicocele, and since that time the left testicle had been much smaller than formerly. Fourteen years ago he had had a gonorrheal urethritis. Sixteen years ago he had eczema on the right hand, which involved also the forearm and popliteal spaces. Since having an attack of ptomaine poisoning eight years ago he had had cramps in the various muscles of the body on starting to move, especially in a cold room when undressing. These cramps started in the calf muscles. About three years ago the patient noticed that he became muscle bound on attempting to lift objects with the left arm, and this at times was painful. For a number of years he had had difficulty in maintaining his balance in the street if he collided with anything, even a child. If a support gave away he was unable to recover himself quickly and fell, and he was unable to rise unassisted from a crouching position. His speech was not quite as fluent as formerly, owing to the fact that his throat became stiff and he was unable to relax the muscles when he attempted to speak. For about a year he had had a limp, his toes dragging on the ground, and for about six months there had been an extensor cramp if the hand was held in one position for a time. The patient used alcohol, tobacco, tea, and coffee in moderation. Physical examination showed the thoracic and abdominal viscera normal. The thyroid was not palpable and the testicles were very small. There was an atrophy of the left sternocleidomastoid, the deltoid, and the biceps muscles. His muscular strength was fair. The myostatic irritability was fascicular. The flexors of the left foot were weak, the reflexes all exaggerated, the vasomotor control poor, and there was a dermatography, but sensations were not disturbed. The electrical reactions, which were verified by Dr. Abrahamson with the Faradic current, showed that the left trapezius was myotonic; the posterior portion of the deltoid gave no reaction; the anterior portion a fairly prompt reaction with twitchings. The left triceps gave a prompt reaction, easily exhausted and followed by twitchings. There was slight myotonia. The left biceps was preatrophic and myotonic. The muscles of the forearm gave a normal response. Nerve point stimulation gave a prompt reaction, followed by twitchings, though less than from muscle stimulation. On the right side the Faradic current showed a beginning reaction of exhaustion in the deltoid. In the lower extremities there was a myotonic reaction in the quadriceps extensors on both sides. There was no reaction of degeneration. Erb's wave reaction from cathode to anode was obtained in both biceps. Examination of the urine on several occasions showed a reducing substance which did not ferment with yeast. The Wassermann reaction and the complement fixation test for gonococci and streptococci were negative. The patient had atrophic testicles, one of which was attributed to varicocele. Whether the condition was to be attributed to deficient hereditary endowment or, with Bramwell and Addis, to a deficient testicular secretion, were questions of vital importance to the patient. In the present instance it was proposed to supply the hypothetical deficiency by implantation of a testicle.

DR. FOSTER KENNEDY said he would hesitate to call the case one of myotonia atrophica. The left sternomastoid was strong, although smaller than the right. The atrophy of the shoulder girdle was confined to the shoulder girdle muscle. In myotonia atrophica the most constant features were the tonus of the supraorbital muscles and of the masseter, and in most cases when the hand was squeezed the fingers opened slowly. Of course he had not seen this case long enough to say that it was not one of myotonia atrophica, but it was different from the types that he had seen. He had noticed a constancy of the tonus of the forearm, which prevented the patient from extending the hand quickly, which was not found in this case. About 70 per cent. of those having this condition had a definite family history of similar disturbances and an also characteristic bilateral cataract occurring prematurely at about the age of thirty-five years.

The following contributions were from the medical wards of St. Luke's Hospital:

Reports of Cases of Tabes Dorsalis Treated by Injections of Salvarsanized Serum Intraspinously.—Dr. AUSTIN W. HOLLIS reported these cases, which were treated first with neosalvarsan intravenously and then by salvarsanized serum intraspinously, after the method of Swift and Ellis. In this series there were fifteen cases, about three-fifths of which were treated with 60 per cent. serum in normal salt solution; in about one-fifth 40 per cent. serum was used, and in the other fifth pure serum. In one case 0.05 c.c. neosalvarsan was dissolved in the serum. The average quantity of neosalvarsan, however, was 20 c.c.; in a few cases 10 or 15 c.c., and in one or two as much as 30 c.c. The smaller amounts had to be given sometimes because sufficient blood could not be obtained to prepare the serum. The reactions following the injections were usually slight, perhaps one or two degrees of fever for two days, nausea or vomiting, and pains in the legs. The pains seemed to be due more to the amount of serum injected than to its strength. In many cases there was practically no reaction. The largest number of injections in any one case was eight. Several patients were injected intensively at intervals of one week for three or four times, but in most of the cases the injections were spread over periods of one to four months. The Wassermann reaction was blood positive in eight cases and spinal fluid positive in eleven cases. In three cases the blood and spinal fluid became negative at the end of treatment. The butyric acid test was positive in ten cases; the Fehlings reduced in three cases. The number of lymphocytes per c.m. in the spinal fluied varied in the different individuals in the series from four to 277 at the time of admission; from two to twenty at the time of discharge, showing a reduction to normal in practically all cases. In three of the cases the knee jerks returned, and in two others light reflex returned. Nearly every patient gained in weight, but rest and hospital care might account for many of these gains. After reviewing in detail these fifteen cases the writer concluded as follows: (1) Intraspinous injections of salvarsanized serum were a perfectly safe procedure, but required experience, a very refined technique, and most careful asepsis. No untoward effects or depressing reactions following any of the injections had been observed. (2) The amelioration of tabetic pain, reduction of the cell count to normal in practically every case, disappearance of the Wassermann reaction in three cases, but above all the return of the knee jerks in three cases and light reflexes in two showed that they were dealing with some curative agent or principle. It was probable that salvarsan alone or in combination with the use of mercury would produce such results. It had been assumed that the salvarsan in the serum might have some potency, but that seemed hardly possible, owing to its extreme dilution. The antibodies in the serum might be of some value but the author was inclined to believe that the withdrawal of the spinal fluid and the introduction of the serum produced vascular and cellular changes in the cord and meninges which enhanced the action of the antisyphilitic remedies given intravenously or intercutaneously. They had seen no case that at this period might be called cured or arrested.

DR. HOMER F. SWIFT said that among the reports made during the past year, that of Dr. Ayer of Boston was most interesting. Dr. Ayer has treated a series of patients with salvarsan intravenously and with mercury, in whom there was some improvement, but when the condition became stationary, combined intravenous and intraspinous methods were used with rather striking improvement. Lately Dr. Ellis and Dr. Stillman of the Rockefeller Hospital have been treating some patients intraspinously simply with normal serum. Some of these patients gave evidence of marked improvement, showing that the serum itself was beneficial. With this newer evidence and that previously obtained, they might attribute the beneficial effects to one or all of the four factors: (1) to the salvarsan content of the serum or to some salvarsan derivative brought about by some reaction between salvarsan and

serum; (2) to anti-bodies; (3) to an increase in the permeability of the meninges brought about by the inflammatory reaction set up by the injection of serum; (4) to the beneficial effect of acute inflammation on top of the chronic inflammatory process,—much like Bier's hypermia treatment of other chronic inflammatory conditions. The speaker said that he was glad to hear that Dr. Hollis had observed no bad results from the injections, and emphasized the fact that such treatments were to be undertaken only with the greatest care, and to be used only after other methods had been exhausted or in rapidly advancing syphilitic disease of the central nervous system.

Report of a Case of Disseminated Myelitis of Doubtful Origin.—Dr. Ewen Van Kleeck read this report for Dr. Lewis F. Frissell. The patient was a single woman, 32 years of age, admitted to St. Luke's Hospital on March 12, 1912, complaining of inability to move the left leg, and weakness in the right leg. Her family history was negative as regarded nervous diseases. Her habits were good and her past history without bearing on her present illness. Two weeks before she had a cold in her head and for the past ten days had felt fatigued in the morning and had indefinite pain in the back. Six days before she had noticed that there was diminished tactile sensation in the left leg, and pricking and tingling sensations from the knee down, with burning pain if the skin was touched; at the same time there was pain in the right eye, and vision became blurred. The bowels had been constipated and for three days previous to admission there had been retention of urine. Physical examination showed no dyspnea, cyanosis or jaundice, and the woman did not appear acutely ill. There was a raised papular and erythematous eruption on the back and buttocks, and to a less extent on the buttocks. There was no rigidity of the neck or enlargement of the lymph glands. There was moderate optic neuritis in the right eye, the edge of the disc being blurred in its entire circumference. There was also slight optic neuritis in the left eye. The color fields of the right eye were contracted; the fields in the left eye were not so markedly contracted. The upper extremities were normal except for the grip in both hands; there was no impairment of power in the upper arm. The left leg showed drop foot and flaccid paralysis from the hip down. There was weakness of the whole right leg, without paralysis. Knee jerks and plantar reflexes were not obtainable and there was no Kernig's sign. The clinical picture was that of a disseminated myelitis, closely resembling a poliomyelitis. The blood count was normal, the leucocytes being 8,000 and the polymorphonuclears 65 per cent. Lumbar puncture obtained a clear fluid with some increase in pressure, showing a cell count of 196 per c.c.; 100 per cent. lymphocytes and a positive butyric acid reaction. The Wassermann reaction was positive on March 21. A second lumbar puncture on March 22 showed the cell count to be 80, with both negative acid and Wassermann reactions, a very rapid clearing of the fluid and one quite characteristic of poliomyelitis.

On March 26 the patient regained a little movement in the toes of the left foot and from that time her paralysis improved gradually until May 28, when she was discharged, being able to stand and walk fairly well. Her upper extremities were normal and knee jerks had returned. Bladder control had been completely regained. The optic neuritis had improved. During her stay in the hospital she had received eight doses of one-half grain of mercury salicylate and also iodides for a short time. The protective action of the patient's serum against poliovirus was tested on monkeys through the courtesy of Dr. Flexner and Dr. Clark of the Rockefeller Institute, with the result that the serum protected against three times the fatal dose of the virus. The patient was at present under the care of Dr. Hollis and showed no symptoms whatever. This case was obviously open to several diagnoses. Evidence of a diffuse lesion did not make the diagnosis of poliomyelitis improbable. The recovery seemed too rapid for a syphilitic lesion treated only by mercury for so short a period and without a positive Wassermann in the spinal fluid. Then, too, research workers at the Rockefeller Institute had recently determined that a positive blood Wassermann was not an unusual event in poliomyelitis, though whether a serum reaction would last two years was doubtlful. The evidence of the protective properties of the patient's serum could not be considered positive, because the patient might have had an abortive attack in the past, or the sera of certain normal individuals might protect. The rapid return of the spinal fluid toward a normal count with the absence of the Wassermann and butyric acid was too speedy for a specific lesion. Second, the case might be one of disseminated syphilitic lesions. The presence of the blood Wassermann after two years was suggestive, and the spinal fluid apart from the absence of the Wassermann might also incline one to make this diagnosis though the rapid recovery made it unlikely. Third, an infectious myelitis of unknown origin had been described by Oppenheim which clinically could scarcely be distinguished from poliomyelitis and which he separated from it on pathological and anatomical grounds, being inclined to limit the term poliomyelitis to a lesion involving the gray matter of the anterior horns. Oppenheim had nothing from a positive point of view to offer as an etiological factor in these cases, and only the negative evidence of the site of the lesion. It seemed fair to make a diagnosis of probable poliomyelitis in an individual who had a concomitant syphilitic lesion, not involving the central nervous system.

Dr. Bernard Sachs said that this report was in line with his observations. Two or three years ago he had reported a case of acute transverse myelitis due to the virus of poliomyelitis. This diagnosis had been arrived at with the aid of blood tests made at the Rockefeller Institute. Since that time some doubt had been thrown on the findings in that case and the reason he spoke of it was that this winter they had had three or four cases of this sort at Mount Sinai Hospital which had to be labeled acute transverse myelitis of infectious origin. Two came into the hospital with the most pronounced symptoms and went on to complete recovery within eight weeks, and had remained well ever since. At the same time there was one case, much more severe, which terminated fatally. The symptoms were those of acute transverse myelitis beginning in the lumbar region, but later becoming more extensive. At autopsy every possible known method was employed to determine the kind of infection present in this case but all to no avail. It was evident, however, that anatomically the spinal cord lesions were not those of poliomyelitis. A toxic or infectous myelitis might lead to recovery, but in this instance it proved fatal.

Detection of Mercury in the Excreta.—Dr. Karl M. Vogel read this paper, in which he said that instances of bichloride poisoning were very frequent, both because of the newspaper notoriety which had made this method of suicide popular and because bichloride tablets were kept in almost every house as an antiseptic. It was very important, both from the standpoint of diagnosis and from that of treatment, to determine whether the patient had really taken bichloride of mercury. Frequently patients came with an obscure or unreliable history, and it was important to settle the question, as the strenuous eliminative treatment required to combat bichloride of mercury poisoning occasioned a great deal of discomfort to the patient and to those who cared for him. Most of the methods of determining the presence of mercury in the excreta were impractical because of the length of the chemical process and the rare chemicals that were required. In St. Luke's Hospital they had had seven cases of bichloride poisoning in the past few months and determined to try to devise a method for detecting the presence of mercury in the excreta by adapting the methods in use. The following method they had found to be reliable and practical: To 150 or 200 c.c. of urine add 5 c.c. hydrochloric acid and evaporate to 50 c.c. Oxidize this by adding two drams of potassium chlorate and continuing to heat until it became colorless. It might be necessary to add more hydrochloric acid and potassium chlorate. Then add water to bring the quantity up to 60 or 70 c.c. and boil to drive off the chlorine. If feces have been used filter at this time. Next a copper wire which had been cleansed in hydrochloric acid was dipped into the fluid, when the mercury would be deposited on the copper. If mercury was present the wire would be covered with it, but it was possible that the deposit might be any of a number of other metals. To prove that it was mercury obtain a small pellet of gold foil from a dentist and place it in test tube; then holding the wire near the pellet, but not touching it, heat, and if the deposit on the copper wire was mercury it would distill over and one would get silver enamel on the gold. A further proof was to use iodine vapor, and red iodide of mercury would be formed. A quantitative analysis might be made by weighing the copper wire before it had received the deposit and afterward, having conducted the first part of the experiment along quantitative lines. This method was applicable to a test of the urine, stomach contents

and feces. The presence of mercury had been proved in twelve instances in which persons had taken two grains of calomel. Of course one should always inquire before making the test whether calomel had been taken.

Treatment of Bichloride Poisoning.—Dr. HENRY S. PATTERSON reported that of five cases of bichloride poisoning coming under his observation the first two occurred by way of the vagina, in one instance one tablet having been used and in the other two. When the first case came in they tried to formulate a method of eliminating the drug so rapidly and in such a dilution as not to set up inflammation of the kidneys. They had used rectal lavage and large amounts of diuretics. The patients left the hospital after two weeks, and at the end of two years were in good health. In the cases poisoned by taking bichloride by way of the mouth one took three tablets and two took two tablets. The method of treatment was largely determined by the findings of the examination of the urine and stomach contents by Dr. Vogel's method. He first gave alkaline diuretics hourly and administered the Murphy drip. Potassium acetate, one dram to a pint, and a milk diet, one glass every two hours, was administered until the stools and urine were free from mercury and remained so for two successive days. He adopted the use of stomach lavage two or three times a day in all patients who came under observation before anuria had developed. In a case seen recently there had been anuria three days and the cause was not suspected. The patient had come home highly intoxicated, and his wife remembered afterward seeing the bottle of bichloride tablets in an unusual situation and the cork removed. When first seen the man did not look sick enough to have a high-grade nephritis. There was no pupillar reflex and it was thought at first that the anuria was a calculus anuria. The stools were examined and gave a strong reaction. The anuria continued two days more, making five days in all; then the patient passed one dram, then two drams, and then five drams of urine on successive days. He then passed 50 ounces and it was thought he was on the way to recovery, but about five days later he developed jaundice and a diphtheritic colitis, which had frequently been recorded as occurring after copious urination had been established. The speaker said that at the present time he had a few cases under observation. One case had been admitted to the hospital on March 26, having taken four bichloride tablets; four or five hours after admission albumen and casts were found in the urine; it was probable that she had a kidney lesion and tertiary syphilis. Anuria continued until April 2, when she passed a small quantity of urine; the quantity increased until by April 9 she passed 49 ounces. On April 17 she passed 78 ounces. Every stool and every specimen of stomach washing up to April 17 showed a strong reaction for mercury. The question was whether she was going to be able to eliminate the drug in a form sufficiently dilute not to cause liver or colon lesion. One could not tell this yet, but the cases he had seen had all succumbed after having had anuria in spite of the establishment of the urinary flow. Another patient was admitted to the hospital on April 9, having taken 30 grains of bichloride in instalments. She had not had anuria; the lowest output of urine was 38 ounces. The phenosulphonaphthalein test at first gave a return of 66 per cent, and on April 21 of 62½ per cent. The outlook in this case was better than in the former one, but the patient had taken the mercury in successive doses and that militated against her recovery. They had produced a high diuresis, 150 to 200 c.c. per day. Of course when they got the patient a few hours after the drug had been taken the outlook was better than when a longer time had elapsed. As to the subsequent effect on the kidneys Dr. Patterson said he had not studied many cases, but in one instance the phenolsuphonaphthalein test gave 76 per cent. after the anuria had cleared. The patient should not go out of the hospital until there was no evidence of kidney irritation.

The Difference in the Morphology of the Blood in Gastric Ulcer, Duodenal Ulcer, and Chronic Appendicitis.—Dr. G. A. FRIEDMAN presented this paper, the object of which was to show that correct interpretations of blood findings in gastric and duodenal ulcer and chronic appendicitis might be of great aid to the clinician in the differential diagnosis of these affections, especially in cases in which all hitherto known methods of examination, including the *x*-ray, had failed to clear up the situation. While partial attention had been paid to the blood in appendicitis this could not be said of the blood in ulcers of the stomach and duodenum. Their hematological studies had convinced them that the morphology of the blood differed in gastric ulcer with the site of the lesion in the viscus. In patients with pyloric ulcers the blood picture varied from that of nonpyloric ulcers. As cases without operative demonstration might be open to criticism their deductions were based on forty-five cases operatively demonstrated. This series of cases drawn from the Vanderbilt Clinic and Dr. Friedman's private practice comprised twelve cases of gastric ulcer, ten in males and two in females; eighteen cases of duodenal ulcer, fifteen in males and three in femals, and fifteen cases of appendicitis, eight in males and seven in females. After citng the operative findings in each of the cases of gastric ulcer and giving the blood picture in each case the author divided these cases of ulcer into two groups: (1) Nonpyloric, where the lesion was at the lesser curvature, nearer the cardiac orifice, and (2) pyloric, where the lesion was at the pylorus or very near to it (para or prepyloric). The average percentage of hemoglobin for the nonpyloric group was 85 per cent., for the pyloric 65 per cent., and the average percentage of hemoglobin for the entire series of gastric ulcers was 75 per cent. The average number of red blood corpuscles for nonpyloric ulcers was 5,700,000, while for pyloric ulcers it was 4,463,000, an average of 5,081,000. The somewhat higher counts of red blood corpuscles in two of the cases in the pyloric group were probably due to concentration of blood, as frequent vomiting was noted in the histories of these cases. Mild leucocytosis was present in the nonpyloric group; in the pyloric group there was no leucocytosis, but frequently a leucopenia. A relative lymphocytosis was frequently found in the pyloric group; there was no lymphocytosis in the nonpyloric group. Small mononuclears were markedly increased in the pyloric group, but showed no increase in the nonpyloric. Any marked increase in the large lymphocytes was not noted in either of the two groups. Large mononuclears were absent from the blood in the two groups. A relative eosiniphilia (4 per cent. or thereabouts) was present in the pyloric group with the exception of one case, a case of pyloric obstruction. There was no relative eosinophiila in the nonpyloric group. There was an occasional increase in transitionals in the nonpyloric group, but no increase in the pyloric. The chief characteristics of the pyloric group were then ologoglobulia, relative lymphocytosis, and relative eosinophilia; of the nonpyloric group, polyglobulia and leucocytosis. The tables showing the operative findings in duodenal ulcers indicated that the lesions were all in the first portion of the duodenum. In eight cases callous or indurated ulcers were found; in four, scars; in two, broad adhesions between the duodenum and gallbladder without stones. A summary of the blood findings in these cases indicated that the average percentage of hemoglobin for duodenal ulcer was 90 per cent. The average number of red blood corpuscles, 6,000,000. Polycythemia was found in fifteen cases out of eighteen, or in 83 per cent. There was no leucocytosis present except in a case shown before to belong to the nonpyloric group and in a case of perforated ulcer. Occasionally leucopenia was present. There was no relative lymphocytosis. An increase in small mononuclears was rarely noted. Relative eosnophilia (4 per cent. and over) was marked only in two cases. Large mononuclears were absent in all the cases of duodenal ulcer except in two in which appendicitis was likewise found. An increase in transitionals was noted frequently. The blood of the patients who continued under observation after gastroenterostomy was examined at longer or shorter intervals after the operation and remained the same with reference to polycythemia and other findings. The characteristics of nonhemorrhagic ulcer were polycythemia, absence of relative lymphocytosis, and absence of relative eosinophilia. After reviewing the operative findings and the blood picture in each of the fifteen cases of appendicitis the author stated that in these cases the stomach, duodenum, and pancreas were explored and found to be normal. In doubtful cases the appendix was examined by the pathologist and found to be diseased. In this series the average hemoglobin was 83 per cent. and the average number of red blood corpuscles, 5,181,000. In three cases polycythemia was found, although the hemoglobin in one case was much lower in comparison with the number of red blood cells. The frequency of polycythemia in this series of appendicitis cases was therefore 20 per cent. In the remainder the red cells were normal or below normal in number. Leucocytosis was found in nine cases, or in 60 per cent., and in one case marked leucocytosis. The frequent occurrence of large mononuclears and the increase in transitionals was noted. The large mononuclears were absent in only

three cases of appendicitis. The chief characteristics then of the blood in appendicitis were large mononuclears, transitionals, and leucocytosis. The blood in nonpyloric ulcer was related to the blood of duodenal ulcer so far as erythrocytes, lymphocytes, eosinophiles, and transitionals were concerned, but differed in regard to white blood corpuscles. The presence of leucocytosis in nonpyloric ulcer made the blood in this condition related to appendicitis. The most striking difference was found between the blood of pyloric ulcer and nonpyloric and duodenal ulcers. The difference in the morphology of blood had led him to construct types of blood pictures in these conditions. The blood picture of appendicitis, although it had the special characteristic, large mononuclears, which were absent from the blood in ulcers of the stomach and duodenum, did not represent a special type but a combination of types. The following types were possible in appendicitis: duodenal, pyloric and nonpyloric, duodenal and pyloric, duodenal and nonpyloric. The author cited cases illustrating the value of blood findings as interpreted by him for the differential diagnosis of the conditions under discussion. In the differential diagnosis of gastric and duodenal ulcer and appendicitis the history, the physical examination of the abdomen, the analysis of the gastric contents and of the feces, and finally the *x*-ray findings, gave valuable data, but none of them seemed to stand in definite relation to the site and character of the lesion in the great majority of cases. The blood findings, on the other hand, seemed to possess such a relation. The author urged his hearers to apply his findings to their own material so as to convince themselves of their definite value in diagnosis.

Dr. CHARLES H. PECK said he would like to confirm the statement made in regard to the great frequency of polycythemia in duodenal ulcer. The difference in the blood picture in duodenal ulcer and appendicitis was quite striking. This difference should prove of value in those cases of appendicitis with gastric symptoms in which the diagnosis was so often in doubt.

Eventration of the Diaphragm.—Dr. MORRIS MANGES and Dr. H. WESSLER presented this communication. Dr. Manges described in detail two cases which represented clinically two well-defined groups of symptoms which, among others, might occur as the result of an abnormality in the structure and function of the diaphragm. These symptoms were referable on the one hand to the respiratory and cardiovascular system, and on the other to the gastrointestinal tract. Frequently these were combined in varying degrees of severity. The first case represented a common symptom complex. Under the influence of trauma, or unusual distention of the abdominal viscera with gas, the already weakened and stretched diaphragm became the seat of further insult and the patient experienced a gastric crisis very much like that occurring in sudden pneumothorax or the onset of a pleurisy, dyspnea, pain, cyanosis, and cough which depended probably also on the extreme displacement of the heart and the blood vessels and the resulting interference with the circulation. These attacks simulated pleurisy and pneumothorax in their physical signs also, there being loud or dull tympany over the chest, immobility of the chest in respiration, succussion, and dextrocardia. So frequent and striking was this association of symptoms that not infrequently these cases were aspirated for fluid, a procedure not devoid of danger of perforating the distended stomach. These crises were followed by sticking pain in the back, dyspnea, and palpitation on exertion until they were succeeded by another acute attack. In the gastrointestinal type, owing to the chornic dilatation of the stomach and also to periodic partial obstruction of the splenic colon in the cul-de-sac of the atrophic diaphragm, the patient might suffer from dyspnea and recurring attacks of intestinal obstruction. If these symptoms were combined with a loss of weight and a severe anemia it was easy to see how a suspicion of carcinoma might be entertained. In the second case the gastrointestinal symptoms were preceded for some years by definite cardiac symptoms which were attributable to the extreme dextrocardia which was present. It had been a subject of contention ever since this subject had been discussed whether in a given case the integrity of the diaphragm, however thinned out it might be, was maintained, or whether there was a real hiatus through its musculature. This question could not be determined definitely by roentgenology, as the wall of the distended stomach presented exactly the same appearance as the line of the thinned dome of the diaphragm. The presence or absence of movement of the diaphragm had not helped to decide this question. The etiology of eventration of the diaphragm was obscure. Hoffman believed that "chronic idiopathic dilatation" of the stomach led to a rudimentary eventration of the diaphragm. Koninger did not favor this view, but with Arnsperger considered the condition one of fatty degeneration of the diaphragm perhaps in the sense of a pseudomuscular hypertrophy of congenital origin, in which later traumatism played some indetermined rôle. Autopsy findings had disclosed a condition of extreme atrophy with fatty degeneration of the muscular fibers, so that the diaphragm had the appearance of a thin membrane. The condition had also been observed in poliomyelitis. The theory of primary disease of the phrenic nerve had not been supported by autopsy findings. Eventration of the diaphragm being easily mistaken for other conditions, it was important in the first place in every case of apparent dextrocardia to look for the presence of diaphragmatic anomaly. Similarly every case which had the clinical signs of pneumothorax should be subjected to a radioscopic examination to avoid the possibility of error. Occasionally diaphragmatic pleurisy and pneumonic lesions at the base of the lungs resulted in an unilateral paralysis of the diaphragm, producing some of the symptoms of eventration. This condition was, however, transitory. From the point of treatment the differential diagnosis between diaphragmatic hernia and eventration was of practical importance. The former condition was amenable to operative treatment, while the treatment of eventration could only be palliative. It was not possible to do anything to restore the function of a completely atrophic diaphragm. On the other hand, anything that increased the intraabdominal pressure would add to the difficulties of the already displaced diaphragm. It had also been noted that associated with an increase in weight and with presumably an increase in the amount of intraabdominal fat, the symptoms were aggravated. It would therefore seem rational to put such patients on a diet in which the fattening elements of the food were restricted and to avoid such foods which by their fermentation would give rise to flatulence.

Dr. H. WESSLER gave a lantern slide demonstration of the cases cited by Dr. Manges. The radiograph of the first case showed a distinct linear curved shadow surmounting the very much distended stomach, which tempted one to believe must be a thinned out diaphragm. That it was much thinned out and atrophied must be assumed from the entire absence of respiratory movement and from the paradoxical movement on breathing. In the second case there were several points of interest which suggested the possibility of diaphragmatic hernia. The thin shadow which should have represented the diaphragm had not the regular curvature which was seen in the first case, its apex being somewhat pointed. The stomach when outlined with bismuth showed a constriction at its lower pole which might be due to the pressure of the margins of the diaphragm. The illustrations well illustrated the difficulties of making a diagnosis of eventration of the diaphragm by means of the *x*-ray.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 24, 1914.

DR. ASA B. DAVIS IN THE CHAIR.

Broken Glass Catheter Removed from the Bladder.—Dr. FORBES HAWKES reported this case. The patient had been catheterized, and the catheter on being withdrawn broke and a piece was left in the urethra. The house surgeon attempted to grasp it but broke it into one or two pieces. A No. 12 Kelly's instrument was then passed and the remains of the catheter came into sight, lying transversely in the bladder. The forceps was introduced, and the catheter grasped and removed. There was no bleeding and the patient had done well.

Carcinoma of the Kidney Associated with Calculi.—Dr. FORBES HAWKES presented this specimen which he had removed from a woman, 29 years of age. She had given birth to twins eight years before and had had convulsions six or seven days after which were typically epileptic in character. The trouble was supposed to be syphilitic in origin. There were no urinary symptoms whatever. She gave a history of tumor of the liver and there was a large tumor on the right side. This was supposed to be a gumma. The Wassermann reaction was negative. The *x*-ray showed the presence of a stone in the right kidney. At operation the kid-

ney was found to have a large cystic sac containing hardened material. The patient was in no condition to stand an operation but did fairly well for eight to twelve days, when she died of exhaustion. The liver was found studded with hard nodules. The kidneys were of the hydronephrotic type.

Carcinoma of the Rectum.—Dr. FORBES HAWKES presented this patient, a woman 57 years of age, who had borne one child. She had had occasional headaches but had never been constipated, and no history of tuberculosis or syphilis was obtainable. Her husband had tuberculosis. Two years previous to her present illness she had had some rectal pain and distress and passed some blood. On examination an annular flat growth involving the rectovaginal septum was found. The operation was performed in two stages, an artificial anus being made first, and later the growth was removed together with the coccyx and a portion of the sacrum. An uneventful recovery followed and the artificial anus had been closed.

Acute Infectious Myelitis Complicating Pregnancy.—Dr. ROBERT E. POU reported this case. He stated that a case of this kind was of such rare occurrence and this one was so well defined that he believed it would be of general interest to the Section. It was more usual to see these cases as the result of caries or syphilis. He had assumed that this case was one of acute infection of the spinal cord, probably a severe myelitis. As a matter of fact the real diagnosis of such cases was usually made at autopsy. The subject of this report was 42 years of age and at the time of the onset of the myelitis was in the sixth month of her fifth pregnancy. The past history of the patient was unimportant; there was no history of miscarriages. During the first week in December, 1913, she became constipated, had headaches, pain in the abdomen and epigastrium, and stiffness in the arms, shoulders, and neck. Not many hours after this she noticed that her legs were numb and helpless, and incontinence of urine and feces followed. A few days later she was admitted to the Lying-In Hospital at which time she was paraplegic. When the writer saw her one week later she was covered with fine scales which seemed to be a congenital ichthyosis. There was no photophobia, or hyperesthesia, and no pupillary symptoms. The muscles of the face and tongue were normal. There was a slight Kernig's sign. Babinski was present in both feet, and knee jerks could be faintly elicited. At the time of her admission to the hospital her temperature was 101°F., pulse 120, and respirations 24. The following day the temperature dropped to normal and then beginning to rise two days later, rose to 103°F. on her ninth day in the hospital. A spinal puncture done on the third day after her admission to the hospital was negative as was also the Wassermann test. The blood count at this time was as follows: hemoglobin 80 per cent., red blood corpuscles 3,890,000, white blood corpuscles 20,800, polymorphonuclears 88 per cent. Examination of the urine showed a specific gravity of 1016; albumin was present, but no sugar and no indican. Urea was 1.9 per cent. There were a few granular and hyaline casts and a small amount of pus, together with some epithelial cells and urates. Ten days after admission the leucocytes were 9,200 and the polymorphonuclears 89 per cent. The leucocyte count diminished until on the twenty-first day in the hospital it was 8,000 and the polymorphonuclears 84 per cent. Labor was induced on December 20 as the patient had bad incontinence of urine and a bedsore threatened to develop over the right trochanter. On December 21 the patient was delivered of a six months macerated fetus. She then made an uneventful recovery. The power returned rather rapidly to both legs and the knee jerks increased at the same time, though the stiffness and retraction of the neck continued for two or three weeks. The incontinence of urine gradually lessened. At no time could any sensory symptoms be elicited. On February 22, after returning to her home, the patient complained of distinct girdle sensations in the region of the ensiform. She hobbled about her room in a peculiar ataxic manner. Several further examinations showed a negative Wassermann, a negative globulin estimation, and only fifteen cells to the millimeter. The urine remained about as at the time of admission. Accounts of a so-called toxic form of myelitis occurring especially in pregnancy were vague and unsatisfactory. To distinguish between it and the infectious type was impossible. The presence of the dead fetus would have to be considered. The treatment consisted mainly in emptying the uterus, preventing bedsores, cleanliness, and turning the patient many times during the day. Urotropin was given to prevent cystitis. Massage and electricity were indicated later on. The prognosis was best in just such cases as the one reported as there was incomplete paralysis. The patient would probably always be spastic and have a weak bladder and rectum. Infection in these cases might occur in three ways: (1) As an extension focus from neighboring inflammations, as spinal caries or meningitis. (2) Through the blood stream, as a part of a general pyemia or a purely local phenomenon. (3) Through the lymphatics, Marinesco having traced an infection along the peripheral lymphatics and nerves in a case of gangrene of the leg.

Dr. SIDNEY D. JACOBSON reported a case that he had seen in London, Eng. The patient was a woman with a tumor of the cord, as he thought, in the dorsal region. She had been paralyzed from the waist down for three years. Neurologists pronounced the case one of tumor of the spinal cord. She was pregnant eight and one-half months, and he thought the uterus might have become enervated. However, he was notified one morning that the woman had delivered herself without pain. The baby was perfectly normal in every way and the delivery perfectly normal. It seemed that there must have been a certain amount of muscular power of the abdominal wall and muscles in order to have expelled the fetus.

Dr. GEORGE KOSMAK said he had had the opportunity to follow the case in the hospital and he was impressed by the condition of the mouth as being a possible factor in the woman's condition. There was a fetid condition of the teeth and gums, the mouth being as filthy a one as he had ever seen. Physicians did not pay sufficient attention to the teeth and gums. Oral surgeons had demonstrated in recent years that carious teeth might serve as an entrance of infection. This patient had a severe gingivitis and the myelitis from which she suffered might have had its source from this locality. The death of the fetus did not produce the inflammatory condition which involved the spinal cord. When the fetus was carried long there would be a toxemia rather than a bacteriemia. Dr. Kosmak expressed the conviction that the source of infection in many cases was carious teeth and the fetid condition of the mucous membrane of the mouth.

Dr. GEORGE L. BRODHEAD expressed the belief that the death of the fetus was merely an incident because there were many such cases in which the fetus was retained an indefinite length of time. Once in a long time a case of mild toxemia was met with in which the evidence was sufficient to indicate emptying the uterus.

Dr. ASA B. DAVIS said that what struck him particularly in the case reported was the gain in health. With regard to the bacteriology, one certainly did find bacteria in the spinal fluid. He recalled the case of a girl, 17 years of age, brought into the hospital with marked symptoms of meningitis which increased in severity. She had an injury of the right jaw caused by being thrown against a radiator. She developed an alveolar abscess. She was eight months pregnant. General symptoms of irritability of the brain and spinal cord developed. It was found that this patient had streptococcemia. A cesarean operation was performed and the child lived only a few days. A complete autopsy was made and streptococci found in the meninges of the brain. The infection was probably from the alveolar abscess.

Complete Inversion of the Uterus Following Delivery.—Dr. JOHN HAMILTON TELFAIR reported this case. He stated that the patient was admitted to his service at the Fordham Hospital on June 29, 1913. She had been delivered of a full term child about ten hours before admission. Following delivery she had had a profuse hemorrhage and a complete inversion of the uterus. At the time of her admission to the hospital she was in profound shock. Saline infusions, Murphy drip, and the usual quickly diffusible stimulants were given and the patient began to react. Examination revealed a large bleeding pear-shaped tumor extending 10 c.m. outside the vulva. This was washed off with hot saline solution, and an attempt was made to push it up in the axis of the pelvic inlet. There was a sense of firm resistance, and upon deep abdominal palpation, this was found to be due to a firm circular contraction of the muscle fibers at the cervico-corporeal junction. The patient was given ether to the surgical degree and when relaxed it was found possible to introduce the thumb and three fingers of the left hand into this cup-

like vagina, and it actually dilated as a cervix would do. With the left hand exerting this dilating force through the abdominal wall, upward pressure on the uterus was made on the right lateral wall, and this portion was started on through the cervix; then by continuous pressure the fundus was gradually worked up until the whole inverted mass reduced itself with a snap. The uterus was packed with gauze and the patient returned to bed in a fair condition. About four hours later she again went into collapse and was given a transfusion of blood. The result was remarkably good. She recovered partially from the primary shock and hemorrhage and left the hospital against advice on the third day. She died of sepsis on the seventh day after delivery. From a search of the literature on post-partum inversion of the uterus, it seemed that next to vagitus uterinus, this was the most uncommon accident that could befall the parturient woman. The most striking thing about the statistics was the tremendous difference in the various figures. Braun stated that it happened once in 250,000 labors, while Kehrer gave one case in 2,000 labors. An average made from the statistics of ten different men was one case in 128,766 labors. This condition was undoubtedly extremely uncommon, but happened more frequently than the figures indicated. Practically all the figures were based on hospital records, and undoubtedly complete inversion of the uterus following delivery was relatively more common among the practice of midwives and physicians who would not report the cases.

Dr. GEORGE L. BRODHEAD called attention to the relaxed uterus which followed the Credé method employed in a violent manner. Relaxation also followed long labors and deliveries with low forceps. Dr. Brodhead cited such a case. Upon examination he found the fundus of the uterus down. With the hand in the uterus he removed the placenta and pushed a cup-shaped depression upward. The employment of a violent Credé method was responsible for these cases of inversion of the uterus following delivery.

Dr. JOHN VAN DOREN YOUNG asked Dr. Telfair if he considered the question of hysterectomy in the case which he had reported.

Dr. TELFAIR replied that he thought it possible that hysterectomy might be necessary, but that it would be better to attempt manual replacement first. The question of anesthesia in these cases was important.

Vagitus Uterinus with Report of a Case.—Dr. GEORGE L. BRODHEAD reported this case. He recalled that Telfair had reported a case of vagitus uterinus in the *New York Medical Journal*, October 2, 1913. It was stated at that time that every paper on this subject in recent years had aroused a storm of criticism and sometimes of ridicule. The bitterest criticism usually came from obstetricians of wide experience. At the close of his article Telfair stated that of 44 reported cases more than one-half were operative deliveries, 11 being forceps, 15 versions, and one replacement of the arm and cord. The fetal mortality was 10 per cent, many of the surviving children living only after prolonged efforts at resuscitation. The patient whose case Dr. Brodhead reported was a VII-para, who went into labor March 24, 1911, at 8 o'clock P. M. The first stage lasted ten hours and during this stage the membranes were ruptured artificially. The second stage was prolonged and it was decided to apply forceps. The head was below the brim, the fetal heart from 140 to 150, and the patient's pulse 128. Dr. F. M. Turnbull, the interne in charge of the case, stated that the right hand was introduced to the left ear, and he was about to introduce the left blade when he heard a distinct loud cry from the baby. The cry was heard by Dr. Stilson, the anesthetist, by a woman in the same room, and by another woman in the adjoining room. The cry continued at intervals until the head was extracted thirteen minutes later. The child was in good condition, had a good color, and weighed ten pounds and ten ounces. To the list of reported cases one other could be added which was reported to the New York Obstetrical Society and recorded in the Transactions of that society, 1906-1907, page 257. Dr. Marx stated that he had heard such a cry once before in his experience. When the case was discussed a member of the Society and an eminent obstetrician stated that in his opinion such a cry was impossible. In the case reported there was no doubt in his mind as to the accuracy and reliability of the observers.

Dr. MALCOLM MCLANE said that the case he had reported was an undoubted one. The fetal head was well up in the uterus. There was suction and he was astounded to hear the child cry; the cry continued for several minutes. He had seen many instances in which the child cried while in the vagina and did not think them worth reporting, but in this case the child was well up in the uterus.

Dr. TELFAIR asked if this was an operative case.

Dr. MCLANE replied that the case was being prepared for operation when there was this suction of air into the uterus, which accounted for the cry.

Dr. TELFAIR said that some cases had been explained by attributing the sound to a vibrating fold of mucous membrane.

Dr. BRODHEAD asked when this report appeared.

Dr. MCLANE said it had appeared in the records of the *American Journal of Obstetrics*, probably sixteen years ago. The case had been reported in full before the New York Obstetrical Society about sixteen years ago.

Spontaneous Evolution of Shoulder Presentation.—Dr. GEORGE L. BRODHEAD reported this case. He stated that shoulder presentations were said to occur about once in two hundred labors, and according to Edgar (The Practice of Obstetrics," 4th Edition) spontaneous evolution occurred in about eight per cent. of all cases, if unusually small children, premature births, etc., were included. There were three factors which must be present to make this spontaneous termination possible, namely, large pelvis, small child, and strong uterine contractions. Owing to the rarity of the mechanism the writer felt that these cases would be of interest. The first case was that of a multipara, seven months pregnant, who had been in labor eighteen hours before she was seen by Dr. Bartholomew and the writer. A shoulder presentation was found, the right arm lying in the vagina. Preparation was begun for a version, but in a few minutes the patient was seen to have strong expulsive pains, the arm steadily advanced, then the right chest appeared, then the trunk of the fetus with extreme lateral flexion, next the lower limbs, and finally the opposite shoulder and head of the still born fetus. The child was macerated and measured fourteen inches in length. There was no hemorrhage; the placenta was expressed by the Credé method, and the recovery was uneventful. Dr. Brodhead reported two more cases of spontaneous evolution of shoulder presentation in which the mechanism was exactly the same as in this case. In all of these cases the puerperium was normal, and the infants stillborn.

Dr. CHARLES GOODMAN said that Abderhalden had demonstrated that stimuli, whether experimental, physiological, or pathological, were capable of elaborating "protective ferments" in the blood. He first demonstrated the presence of a specific ferment during pregnancy and this promised to be the key to a vast, but as yet unexplored, field of seropathology. At the Beth Israel Hospital Dr. Beckwith and Dr. Goodman had tried the Abderhalden dialysis technique in various groups of sera obtained from clinical material as well as from animals, and it might be of interest to review their findings in a few of the cases of malignancy. The material had been limited at the Beth Israel Hospital and some of the specimens obtained elsewhere had become contaminated; the presence of hemoglobin in the serum was bound to give misleading results. As more data were collected it would be of intense interest to see how nearly the diagnosis of the presence of malignancy could be elicited, and it was to be hoped that the method would assist in establishing a diagnosis in those obscure cases in which it had been impossible to make a diagnosis by other methods. The series of cases comprised thirteen, of which five had been diagnosed as cancer of the breast, two as cancer of the stomach, and one each of the liver, rectum, face, and femur, There was also a retroperitoneal tumor and a case in which the diagnosis was doubtful. This had been considered a case of possible cancer of the uterus, but the microscopical report had not been made. The cervix had been removed and the Wassermann was positive. The patient improved under the administration of salvarsan. This was the only case in the series in which the serum test was negative; in all the others it was positive.

Dr. S. H. GEIST said that in the chemical laboratory of Mount Sinai Hospital Dr. Epstein and he had been investigating the Abderhalden reaction in pregnancy and had adhered to the technique described by Abderhalden, having been in personal communication with him regarding the work. Their results had been very discouraging, and he felt that other investigators must

have had similar experiences and hesitated to publish them because of fear of the criticism of improper technique. Losee and Jellinghaus, in a large series of cases investigated at the Lying-In Hospital, arrived at a technique which gave them very good results. A subsequent series with the same technique gave bad results. He did not believe that up to the present time the second series had been published. In relation to the test in carcinoma, Dr. Crohn, working in the laboratory of Mount Sinai Hospital, in a fairly large series of cases had very disappointing results. His early cases gave great promise, but the same technique extended to a large series of cases did not result very favorably. It seemed from their experiences that the poor results could not be attributed entirely to faulty technique.

Result of Three Years' Observation on a New Form of Cancer Treatment.—Dr. L. GRANT BALDWIN reported three cases out of twelve that had received 30 c.c. of serum intravenously. One or two of them felt faint after the injection. Two or three developed a severe urticaria which lasted about one week, but did not interfere with their regular work. The first patient had had an operation for carcinoma of the breast two years ago last June and since that time she had gained greatly in strength. He had never seen a case as bad as this left in such good shape after operation and the use of serum. In the second case there was a mass in the lower sigmoid and the gut was immovable, so much so that it was impossible to get beyond it. He thought it better to leave it alone and make an artificial anus, which he did. After reading Dr. Berkeley's article he placed the matter before the husband and consent to an operation was obtained. The patient had since gained twenty pounds and was in comparatively good health. The third patient had rapidly recurring cancer of the cervix. After the operation she was without recurrence for three years, when a rapid recurrence took place. She did well on serum for three or four weeks, when the serum seemed to lose its effect and she succumbed to the disease.

Dr. JOHN VAN DOREN YOUNG reported the case of a woman who started with recurrences two months after an operation on the right side. He took out nineteen nodules at one sitting. He then read Dr. Berkeley's paper, and with Dr. Beebe's help got the stock serum. The results were the most remarkable he had ever seen. There were thirty-five nodules under the skin which disappeared. No more nodules appeared after the first injection of serum. The patient left him because he would not guarantee a cure and went to Spain, where she died, probably of mediastinal carcinoma. The work of Drs. Berkeley and Beebe gave them food for thought and they should help these men in their work. Serotherapy was logical and they should give Dr. Berkeley every case not moribund to work on.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF NORTH CAROLINA.

June 10-14, 1913.

ANATOMY, PATHOLOGY, HISTOLOGY, AND BACTERIOLOGY.

1. Locate and describe the cecum.
2. Give origin, course, and distribution of the seventh nerve.
3. Describe the right and left subclavian veins
4. Describe the diaphragm, its principal openings and nerve supply.
5. Describe the mastoid portion of the temporal bone, and name the muscles attached thereto.
6. Name the ligaments of the hip-joint.
7. Relate the difference between a virgin uterus and the uterus of a multipara.
8. What anatomic parts are involved in the descent of the testes.
9. Describe the lesion found in the different forms of cirrhosis of the liver.
10. Give the gross pathology of amebic dysentery. Describe the organism giving rise to it and name the pathological condition of the liver often associated with it.

Answer only 8 questions.

PHYSIOLOGY AND HYGIENE.

1. What do you consider the chief difference in the function of epithelial and connective tissue?
2. Name classes of foods. (*a*) Which of these is alone capable of sustaining life? (*b*) What chemical element is usually spoken of as the chief characteristic of this one? (*c*) What per cent. of the molecule is composed of this element? (*d*) In the form of what substance is this element chiefly eliminated? (*e*) Where is this substance formed?
3. Name enzymes found in alimentary canal, place found, and function.
4. Give classification of white blood corpuscles and per cent. of each found in normal blood.
5. What is the fluid in muscle tissue called? (*a*) What is its chemical reaction? (*b*) How is this affected by fatigue? (*c*) By death? (*d*) Explain.
6. Trace circulation of blood through kidney.
7. Define Wallerian degeneration.
8. Give distribution of pneumogastric nerve and function in each locality. (That is state class of nerve in each locality.)
9. What is the significance of colon bacilli in drinking water?

MATERIA MEDICA AND THERAPEUTICS.

1. Mention the conditions which affect the dosage of medicines. Name the methods of introducing medicines into the circulation.
2. Give the physiological action of saline purgatives and their therapeutic uses.
3. Name the three most used preparations of opium and state how much of each represents one grain of opium. Explain the constipating action of opium.
4. Name an antidote for each of the following, and state whether this is physiological or chemical: arsenic, opium, copper, and strychnine.
5. State what remedies are used to reduce temperature. Explain how they accomplish this result, and describe how used.
6. What drugs would you use to stimulate the heart's action, to produce emesis, to control hemorrhage, to produce sleep, to relieve pain? Doses of each.
7. Name several drugs that render urine alkaline Give their doses. What class of acids would you use to acidify alkaline urine? Give an example. Give the composition of linimentum calcis and therapeutic uses
8. What is incompatibility in medicine, and what are the different kinds of incompatibles? Give an example of each.

CHEMISTRY AND DISEASES OF CHILDREN.

1. Describe the process of manufacture of chloroform, ether, and nitrous oxide, and express in equations the reactions respectively occurring in their formation.
2. Review briefly the theory of ions or of electrolytic dissociation.
3. The composition of normal urine represents the approximate equilibrium between the *acidic* and the *basic* end-products of metabolism. Name several food substances which contribute to the establishment of *acid conditions*, and several others which contribute, in like degree, to the establishment of *basic conditions*
4. What two sugars are especially concerned in the anabolism of the tissues? What organ converts levulose and lactose into glucose? How would you determine the limit of assimilation of the various sugars?
5. What are fats chemically? In what two ways do fats form in the organism? How is the composition of the fats of the diet affected in the process of digestion and assimilation? What is the significance of excessive unresolved fat and of fatty acid crystals in the feces? What is the final fate of the fat in the body?
6. State the general plan of the enzymotic hydrolysis of the protein molecule, and designate the form which the resulting products must assume prior to absorption and nutrification.
7. Discuss the properties, the relative merits, and the indications for using the various carbohydrates in infant feeding.
8. Describe Kernig's and Babinski's reflexes, and give their respective diagnostic value.
9. Describe congenital atelectasis, and state the best method of remedying the condition.

Answer any six of the foregoing questions

ANSWERS.

ANATOMY, PATHOLOGY, HISTOLOGY, AND BACTERIOLOGY.

1. The *cecum* is a blind pouch which forms the commencement of the large intestine. It is situated in the right iliac fossa, immediately behind the abdominal

wall, and above the outer half of Poupart's ligament. It may lie on or to the right side of the psoas muscle, or in the pelvis; and is of very variable size. Its length may be from two to four inches, and its width about the same. It is generally covered by peritoneum, and is usually freely movable. Its shape is variable, and it is generally classified under one of four possible types. From the cecum is given of the vermiform appendix. The ileocecal valve opens into the large intestine at the point of junction of the cecum with the ascending colon.

2. The *seventh or facial nerve* has its superficial origin in the upper end of the medulla oblongata, in the groove between the olivary and restiform bodies. It passes "forward and outward to enter the internal auditory meatus; it lies upon a groove on the auditory nerve, with portio intermedia of Wrisberg between, and at the bottom of the meatus it enters the aqueductus Fallopii, along which it runs first outward between cochlea and vestibule as far as hiatus Fallopii; then backward in internal wall of tympanum, just above fenestra ovalis, at the turn presenting a swelling, the geniculate ganglion; and finally it passes downward, to emerge from the bone at the stylomastoid foramen; it then passes outward and forward in the parotid, dividing behind the ramus of the jaw into temporo-facial and cervico-facial branches, which further subdivide and intercommunicate, forming the pes anserinus."—(*Aids to Anatomy.*)

It *supplies* the muscles of expression in the face, the muscles of the external ear, the Platysma, Buccinator, Stylohyoid, and the posterior belly of the Digastric.

3. The *subclavian vein* is the continuation of the axillary, and extends from the outer border of the first rib to the inner end of the clavicle where it joins the internal jugular vein, the two forming the innominate vein. At this junction the left subclavian vein receives the thoracic duct and the right subclavian vein receives the right lymphatic duct. The tributaries are the external, and anterior jugular veins. It is separated from the subclavian artery by the scalenus anticus muscle and the phrenic nerve.

4. The *diaphragm* is a musculofibrous septum which divides the thoracic from the abdominal cavity; it is fan-shaped; the broad elliptical portion is horizontal, and the crura are vertical. It is attached to the ensiform, to the internal surfaces of the lower six costal cartilages, to bodies and intervertebral substances of first, second, and third lumbar vertebræ. Its *openings* are: (1) The aortic, transmitting the aorta, vena azygos major, and the thoracic duct; (2) the esophageal, transmitting the esophagus, pneumogastric nerves, and some small esophageal arteries; (3) the opening for the vena cava, transmitting the inferior vena cava, and small branches of the right phrenic nerve; (4) the right crural, transmitting the right splanchnic nerves; (5) the left crural, transmitting the left splanchnic nerves and the vena azygos minor. —*Nerve Supply*: Phrenic, lower intercostals, and sympathetic.

5. The *mastoid portion of the temporal bone* is situated at the posterior part of the bone; its outer surface is rough and has several foramina, the chief of which is called the mastoid foramen and transmits a vein to the lateral sinus and a small artery to the dura. It is continued below into the mastoid process, on the inner side of which is the digastric fossa. The inner surface lodges part of the lateral sinus in the sigmoid fossa. The mastoid process contains the mastoid antrum and the mastoid cells. *Muscles attached*: Occipito-frontalis, sterno-mastoid, trachelo-mastoid, retrahens aurem, splenius capitis, and digastric.

6. The *ligaments of the hip-joint*, are: Capsular, iliofemoral, cotyloid, transverse, and ligamentum teres.

7.

VIRGIN UTERUS.	UTERUS OF MULTIPARA
The cavity is of normal length and triangular.	The cavity is increased in length, and oval.
The cervix is small, hard, and cartilaginous, and of the same length as the body.	The cervix is large and soft; it is about one-half the length of the body.
The external os is a transverse slit or pinhole orifice with smooth edges.	The external os is irregular and its edges are fissured.
The sides of the cavity of the body are convex inward.	The sides of the cavity of the body are convex outward.
The uterus is normally anteflexed.	The uterus is straighter, or even retrodisplaced.
There is more or less flattening of the anterior and posterior uterine surfaces.	The contour of the uterus is more rounded, while its diameters are increased.
The fundus is nearly flat.	The fundus is convex.
The internal os is closed.	The internal os is patulous.

(From Dorland's *Obstetrics.*)

8. *Descent of the Testes.*—"In early fetal life the testes are placed at the back part of the abdomen, below and in front of the kidneys, and behind the peritoneum. About the third month a peculiar structure, the gubernaculum testis, appears, attached to the lower end of the epididymis, and extending as a cord to the bottom of the scrotum. It is supposed to cause the descent of the testicle. It reaches its full development between the fifth and sixth month, at which time the testicle reaches the iliac fossa. It enters the internal abdominal ring by the seventh month, and the scrotum by the eighth month, carrying before it a fold of peritoneum, which is afterward shut off, forming the tunica vaginalis testis. Other coverings of the testicle are also derived in this manner. In the female a structure similar to the gubernaculum forms the round ligament." (Young's *Handbook of Anatomy.*)

9. The following table (from Thayer's "Pathology") will assist in distinguishing the two varieties of cirrhosis of the liver:

Synonyms. Charcot's, Hypertrophic, Unilobular, Hepatogenous, Biliary.	Laennec's, Atrophic, Multilobular, Hematogenous, Hob-nail liver.
Jaundice. Early and marked, bile often absent from feces.	Late and slight, bile usually present.
Ascites. Late and unimportant.	May be early; often enormous.
Spleen. Enlarged early and markedly.	Late and less.
Alimentary hemorrhage, piles. Not common.	Common.
Liver. Large, smooth, mottled, green.	Small, rough, pale or yellow.
New fibrous tissue. In fine lines and strands between acini and cells, involving all parts equally.	In broad bands, making prominent islands in which the single acinus may appear nearly normal; distributed irregularly

10. In *amebic dysentery:* "The lesions are chiefly seated in the intestine. They present: (*a*) Small gelatinous swellings of the mucosa, with partial ulceration; (*b*) Necrosis and sloughing of the underlying tissues. The ulcers of amebic dysentery thus have undermined edges. The amebæ are found in the ulcerating mucosa, but more abundantly in the tissues beyond the ulcerated area (submucous or muscular coat), where they set up edema and necrosis. Later, along with the ulcers, cicatrices, leading sometimes to partial stricture, may be found. Hepatic abscess, usually single, and hepatopulmonary abscess are common complications. Amebæ are sometimes found in the portal capillaries.

"The ameba is a rounded cell with a clear outer ectoplasm, and a granular endoplasm. It has a rounded or oval eccentric nucleus, and measures from 10 to 15 μ in diameter. In the warm stage it shows active ameboid movement. In the resting stage it forms a cyst or cysts, and in this state resists drying for a long time. The organisms are found chiefly in the large intestine, especially in the rectum and flexures, but they also occur in the ileum and stomach, and in the liver. They have the power of penetrating the tissues."—(Wheeler and Jack's *Handbook of Medicine.*)

PHYSIOLOGY AND HYGIENE.

1. The *functions of epithelium* are: Protection, secretion, absorption, special sensation, and ciliary motion.

The *functions of connective tissues* are: Support, connection, and protection.

2. Foods are classified as follows:

Inorganic { Salts / Water

Organic { Nitrogenous—Proteins / Non-nitrogenous } { Carbohydrates / Fats }

(*a*) Proteins.
(*b*) Nitrogen.
(*c*) About 15 to 18 per cent.
(*d*) Urea.
(*e*) In the liver.

3.

ENZYMES.	ORIGIN.	FUNCTIONS.
Ptyalin.	Saliva.	Changes starches into dextrin and sugar.
Pepsin.	Gastric juice.	Changes proteids into proteoses and peptones in an acid medium.
A curdling ferment.	Gastric juice.	Curdles the casein of milk.
Trypsin.	Pancreatic juice.	Changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin in an alkaline medium.
Amylopsin.	Pancreatic juice.	Converts starches into maltose.
Steapsin.	Pancreatic juice	Emulsifies and saponifies fats.
A curdling ferment.	Pancreatic juice.	Curdles the casein of milk.
Invertin.	Succus entericus.	Converts maltose into glucose.

4. *White blood corpuscles are classified* as follows: (*a*) Small mononuclear leucocytes or lymphocytes, about 25 per cent. of the white blood corpuscles; (*b*) large mononuclear leucocytes, about 1 per cent.; (*c*) transitionals, about 2 to 4 per cent.; (*d*) polynuclears, about 70 per cent.; (*e*) eosinophiles, about 2 per cent.; (*f*) and mast-cells, about 0.1 to 0.5 per cent.

5. The fluid in muscle tissue is called muscle-plasma.
(*a*) Alkaline.
(*b*) Acid, due to development of sarcolactic acid.
(*c*) Acid, due to development of sarcolactic acid.

6. *Renal circulation.* "The renal artery, on entering the kidney, breaks up into numerous primary branches, which travel along the columns of Bertini, and are called the arteriæ propriæ renales. These divide at the base of the pyramids and form arches with their neighbors; these arches give off (1) branches into the cortex termed the interlobular arteries, from which the afferent vessels to the Malpighian tuft arise; the efferent vein from the glomerulus breaks up into a capillary network which ramifies on the urinary tubules in the cortex, and after an extended course joins the interlobular veins; the efferent vessels of the lowermost glomeruli break up into and surround the straight tubules; (2) branches downward into the pyramids running between the bundles of collecting tubes, and termed the vasa recta or arteriæ rectæ. The interlobular veins correspond with the arteries, and receive some veins termed stellate from beneath the capsule, and also the small veins which receive the blood from the minute plexus surrounding the convoluted tubes. The venæ rectæ run along the pyramids accompanying the corresponding arteries. The venæ propriæ renales pass along the columns of Bertini after having been joined by the interlobular veins and venæ rectæ."—(Ashby's *Notes on Physiology.*)

7. *Wallerian degeneration:* "When a nerve is divided the first result is a loss of its function. Inasmuch as each nerve-fiber develops from a cell which later nourishes it, if the connection between the two is severed the nerve-fiber undergoes Wallerian degeneration, and in the case of a nerve which is made up of nerve-fibers the whole nerve undergoes this change. This degeneration consists, in the case of medullated nerves, in the death of the axis-cylinder, the breaking up of the medullary sheath into drops of myelin, which are later absorbed, and the multiplication of the nuclei of the primitive sheath. In non-medullated nerves the only result is the death of the axis-cylinder. Degeneration begins very soon after the section—within a day or two—and throughout the entire severed portion of the nerve at the same time. Thus the course of a nerve, or a collection of nerves, may be traced throughout its entire extent. These changes are believed to be due to the severance of the nerve from its trophic center. If an anterior root of a spinal nerve is divided, the distal end, being separated from the gray matter of the cord which is its center of nutrition, undergoes degeneration, while the end which remains connected with the cord retains its integrity. If a posterior root is divided between the cord and the ganglion, the degeneration takes place between the cord and the ganglion; while if divided below the ganglion, the degeneration takes place in that portion separated from the ganglion, showing that the ganglion is the nutritive center for the posterior root." (Raymond's *Physiology.*)

8. *Distribution of pneumogastric nerve:* To dura, external ear, pharynx, heart, lungs, esophagus, and stomach. *Functions:* "Throughout its whole course the pneumogastric contains both sensory and motor fibers. To summarize the many functions of this nerve * * * it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excitosecretory* to the salivary glands; (7) *excitomotor* in coughing, vomiting, etc." (Kirkes' *Physiology.*)

9. The presence of colon bacilli in drinking water is an indication that the water is polluted with sewage.

MATERIA MEDICA AND THERAPEUTICS.

1. *Conditions which affect the dosage of medicines:* Age, sex, weight, habit, idiosyncrasy, method of administration, mental emotion, preparation of the drug, cumulative action of the drug, and the presence of disease.
Methods of introducing medicine into the circulation: By mouth or stomach, hypodermatically, by inhalation, by the rectum, by inunction, by fumigation, intravenously, and intramuscularly.

2. *Salines* stimulate the intestinal glands to increased secretion, and by their low diffusibility impede reabsorption; this results in an accumulation of fluid in the intestinal tract, which partly from the effect of gravity and partly by stimulating peristalsis, causes a copious evacuation.
Salines are indicated in constipation, intestinal putrefaction, dropsy and to lessen the secretion of milk in nursing mothers.

3. Tincture of opium, 10 minims equals one grain of opium; camphorated tincture of opium, about half an ounce contains one grain of opium; Dover's powder, 10 grains contains one grain of opium.

4. *Antidote* for *arsenic*, freshly prepared solution of ferric hydroxide (chemical); for *opium*, potassium permanganate (chemical); for *copper*, potassium ferrocyanide (chemical); for *strychnine*, potassium permanganate (chemical).

5. The following table (from Potter's "Materia Medica") gives the chief antipyretics with their manner of action. Temperature depression may be done by five different actions working upon two principal lines, viz., by:

(*a*) *Lessening heat production, by*
- (1) diminishing tissue change,
- (2) reducing the circulation.

(*b*) *Promoting heat loss, by*
- (3) dilating cutaneous vessels, thus increasing heat radiation.
- (4) promoting perspiration — its evaporation lowering the temperature.
- (5) abstracting heat from the body.

The following list of antipyretics include a few for each of the above-named actions, to which the numbers refer in each case, viz.:

Quinine, 1.	Aconite, 2.	Antipyrin, 1, 4.
Phenol, 1.	Alcohol, 1, 3.	Antimony, 2, 4.
Salicin, 1.	Nitrous ether, 3, 4.	Cold Bath, 5.
Digitalis, 2.	Acetanilid, 1, 4.	Cold drinks, 5.
	Phenacetin, 1, 4.	Wet-pack, 5.

6. *To stimulate the heart's action:* Alcohol ʒss; aromatic spirit of ammonia, ʒj; nitroglycerin, gr. 1/20;

ether, ʒj; heat, applied over the heart; digitalis, extr. gr. j; citrated caffeine, gr. v; tincture of strophanthus, ♏v; strychnine sulphate, gr. 1/20.

To produce emesis: Ipecac, gr. xx; apomorphine hydrochloride, gr. 1/10; tartar emetic, gr. ½; zinc sulphate, gr. xv; copper sulphate, gr. iv; mustard and water.

To control hemorrhage: Wine of ergot, ʒij; adrenalin chloride, ♏v of the solution; fluid extract of hamamelis, ♏xxx.

To produce sleep: Opium, gr. ss; tincture of Cannabis indica, ♏x; alcohol, ʒj; chloral hydrate, gr. xv; sulphonal, gr. xv; trional, gr. xv; veronal, gr. vij.

To relieve pain: Opium, gr. jss to ij.

7. The salts of potassium, lithium, and sodium render the urine alkaline. Lithium bromide, gr. xv; lithium citrate, gr. vij; potassium acetate, gr. xxx; potassium bicarbonate, gr. xxx; potassium citrate, gr. xv; potassium bitartrate, gr. xxx; potassium and sodium tartrate, ʒij; sodium acetate, gr. xv; sodium bicarbonate, gr. xv; sodium, gr. xv.

To acidify the urine: Vegetable acids, in excess, acid sodium phosphate, or benzoic or salicylic acids.

Linimentum Calcis contains equal parts of lime water and linseed oil. It is used locally for burns.

8. *Incompatibility* is that relation between medicines which renders their admixture unsuitable. Incompatibility may be chemical, pharmaceutical, or therapeutic. *Chemical incompatibility* is seen in compounding an acid with a base, and forming a salt. *Pharmaceutical incompatibility* is seen in compounding a resinous tincture with an aqueous solution. *Therapeutic incompatibility* is seen when two agents are administered together which have an opposite action, such as belladonna and physostigma.

CHEMISTRY AND DISEASES OF CHILDREN.

1. *Chloroform* can be obtained by heating chloral hydrate with an alkali:

$C_2HCl_3(OH)_2 + KHO = CHCl_3 + H.COOK + H_2O$

Ether is made by the action of sulphuric acid on alcohol:

$H_2SO_4 + C_2H_5OH = H_2O + C_2H_5HSO_4$

$C_2H_5HSO_4 + C_2H_5OH = H_2SO_4 + (C_2H_5)_2O$

Nitrous oxide is made by heating ammonium nitrate:

$NH_4NO_3 = N_2O + 2H_2O$

2. *Electrolysis and Electrical Dissociation.*—"The molecules of many simple chemical substances, on being dissolved in water, are more or less completely split up or dissociated into two or more (generally two) parts called ions. This behavior of substances, on going into solution, is known as electrolytic dissociation or ionization. The substances which dissociate in this manner are all conductors of electricity, and are called electrolytes; those substances which do not dissociate are non-conductors. When a current of electricity passes through an electrolyte or its solution, the latter undergoes certain changes, which we group under the term electrolysis. The electrodes are the conductors by which the current enters or leaves the electrolyte. Under the influence of an electrical current the ions of the electrolyte migrate in two directions. Those ions which migrate toward and concentrate about the anode (or positive electrode) are called anions. Those which migrate toward and accumulate about the cathode (or negative electrode) are called cathions. Certain gases undergo ionization under the action of the ultraviolet light, Röntgen rays, radium rays or heat."—(Bartley's *Medical Chemistry*).

3. *Acid conditions* of the urine are caused by animal food, restricted fluid. *Basic conditions* are caused by vegetable food, milk diet, and a large amount of fluids.

4. The two sugars are cane sugar and lactose. They are converted into glucose in the liver. When sugar is not assimilated, the excess appears in the urine.

5. Chemically, *fats* are esters of glycerol with a fatty acid; most of them are mixtures of glyceryl tripalmitate, glyceryl tristearate, and glyceryl trioleate.

Fats are formed in the body from the food ingested, chiefly (1) the fats and (2) the carbohydrates.

In the alimentary canal the fat is split up into glycerol and fatty acid, these are absorbed by the cells covering the villi of the intestine and are here again converted into fat.

Excessive fat in the feces is an indication that more fat has been taken in than could be absorbed.

The fats are utilized in the body for the production of force or to be stored as adipose tissue to be used later; they therefore serve for the production or maintenance of heat and for the performance of work. The products of combustion of fat are CO_2 and H_2O.

6. During digestion the proteids are split up into proteoses, peptones, polypeptides and amino-acids. The amino-acids are believed to be taken as such by the epithelial cells and carried to the blood of the portal capillaries. Another view is that in the intestinal epithelium the amino-acids are built-up again into proteins such as are found in the blood. There are three theories of the further history of the proteids. According to one of them (the theory of Voit), "the protein of the tissues, living or organized protein, is to be differentiated from the absorbed circulating protein. It is only in this circulating protein, which is assumed to be present in the fluids of the body, the blood and lmyph, that catabolic changes take place. These changes take place under the influence of the living cells. The more resistant organized protein is not supposed to undergo catabolic changes. If any of it does, it is cast off into the fluids of the body, and thus becomes circulating protein, undergoing catabolic changes in precisely the same manner. It is obvious that a small part of the absorbed protein must be utilized to replace the waste of the organized protein and to subserve the process of growth. This portion is termed tissue protein."—(Lyle's *Physiology.*)

7. The various carbohydrates used in infant feeding are sugars and starches. Sugars, particularly lactose, are useful; but starches should not be given before the period of teething, as the infant is not capable of digesting starches until that time.

8. *Kernig's sign.* The patient lies on his back with the thigh at right angles to the body; he then tries to extend his leg and so bring it into a line with the thigh. In case of cerebrospinal meningitis this is nearly always impossible.

Babinski's sign. If the skin of the sole of the foot is irritated, there will be noticed extension of the toes instead of flexion. It is found in lesions of the pyramidal tract.

9. CONGENITAL ATELECTASIS. "This is a condition in which the alveoli of the lungs have not become filled with air at birth, but remain empty and collapsed. The child makes only faint efforts at breathing, the skin feels cold, and the temperature is only 97°F. The fingers and toes are blue, and the cry is faint; the child is unable to suckle; the pulse is hardly perceptible, and the fontanelle is deeply depressed. Auscultation reveals little air entering the chest, and at the bases and along the borders of the lungs vesicular sounds may be entirely absent. Percussion will give some dullness at the bases and along the borders of the lungs close to the spine. Cases of this severity live but a few hours, but many others, not so extensive, may, by energetic treatment, recover."

Treatment. "Artificial respiration; the warm bath; rubbing the back with whisky; dashing cold water on the chest, are the means used when the child is born apparently lifeless. It is very necessary that the body-heat be maintained, therefore keep the child in a warm room, and roll it in cottonwool. If unable to suckle, it must be spoon-fed, and it should get 5 drops of brandy in a spoonful of hot milk every hour. Stimulating liniments and the mustard-bath are also serviceable, and the inhalation of oxygen may be tried."—(McCaw's *Aids to Diseases of Children*).

(To be concluded.)

Multiple Subcutaneous Cysts in the Arms.—E. Cautley reports a case of a male aged seven months who was the sixth of the family, only one being dead. He had fits at intervals from the age of four days to eight weeks, and again last December. Apart from this he was reasonably healthy, though somewhat rachitic and ill nourished. "Lumps" were said to have been present at birth on the left and right arms and two on the back. They were described as having been purple and hard, and as having been called abscesses. They were also said to have gotten smaller. No new ones had appeared and none had been noted in the other children. There were several nodules, varying in size from a millet-seed to a pea, in the left arm, mainly from the shoulder to the elbow. The skin seemed adherent to the larger ones, but the others were subcutaneous. Two minute ones were present at the bend of the right elbow; on removal these were found to contain clear fluid. The two said to have been present on the back disappeared.—*Proceedings from the Royal Society of Medicine.*

SOME PROBLEMS IN GENETICS.

BY THOMAS E. SATTERTHWAITE, M.D., LL.D., Sc.D., NEW YORK.

GENETICS is a branch of biology that embraces generation in all its aspects, and is deservedly attracting a great deal of attention. As physicians, however, we are more taken up with those phases of it that have to do with the propagation of normal human beings and of the abnormal through procreation. Both of these topics fall, directly or indirectly, within the scope of eugenics, a branch of genetics that is especially interesting us at the present time.

The principles of both, as the latter includes the former, were first emphasized by the laborious but illuminating studies of Lamarck (1809), Wallace and Darwin (1859) on evolution; Mendel (1866) and Galton (1897) on heredity; and in this country more recently by Dugdale (1878) and Davenport, Goddard, and Rosanoff (1911-12). The data furnished by these men and others of their colaborers on these or collateral lines have served to lay down certain general principles that have been successfully applied in the hybridization of plants and in the cross-breeding of animals. But though for various reasons these principles are not as applicable to human beings as to the lower forms of life, they may properly be utilized as bases for solving problems bearing on the legal regulation of marriage and the propagation of hereditary diseases.

Certainly any reasonable person will admit that marriages concern the community at large, sometimes as much as and often more than the contracting parties. Matings of any sort should therefore be amenable to some sort of regulation, whether by moral influences, legal methods, or by arbitrary authority as in the medical departments of our army and navy. In fact, eugenics has so close a relation to the well-being of society that laboratories are devoted exclusively to its study, an international congress has met to further its interests, and legislatures have framed laws to make its teaching effective. There are many illustrations at hand to show its importance, but the history of the notorious "Jukes" family,[1] familiar to many of us, gives an instructive picture of the appalling consequences of improper matings. I will merely outline it. Somewhere between the years 1720 and 1740, a hard-drinking backwoodsman of our State known to us as "Max Jukes," was the first in a family that up to the year 1877, either in direct or collateral lines, by marriage or cohabitation, numbered upward of a thousand individuals. Of these 709 were actually traced in the course of the investigation; 300 or thereabouts were computed to have died prematurely; 50 of the females were common prostitutes; 40 of the women had specific diseases, contaminating 440 persons; 60 were habitual thieves; 7 were murderers; while very many others were in various ways burdens on the State. When the inquiry closed, in 1877, it was estimated that the family had cost the State $1,308,000, or more than a thousand dollars apiece for each of the 1000 persons in whom there had been Max Jukes' blood, besides causing widespread degradation and the physical harm to the community that has been described.

The following history, however, is even more instructive, as it contrasts the results of unfit with fit matings. Back in Revolutionary times a man by the name of Martin Kallikak took advantage of a feeble-minded girl. Of their 480 descendants 143 were feeble-minded, the greater part of the number falling below mediocrity, while none of the remainder had any special ability. Later, Kallikak married a respectable Quaker girl, "of good ancestry," it is said. From this union there were 496 descendants whose histories were traced. All of these but two were normal mentally, and the two exceptions were not feeble-minded. In both the Jukes family and among Kallikak's first set of descendants the breeding seemed to be "true"; that is, the vices or defects of the parent were apparently transmitted to the majority of the offspring, while on the other hand Kallikak's marriage with the Quaker girl, after he had come to look at life from a different angle, was productive of children that were gifted with exceptionally good traits. Other somewhat similar family histories have been published, each teaching the same object lesson. But even from the recital of the two I have mentioned, the conclusion is inevitable that such calamities should in some way, if possible, be prevented, for the protection of society.

Let me now turn to another phase of this subject. As physicians, some of us have to face even more widespread results of ill-assorted matings, which, if they do not cause such obvious damages to society as those in the two families alluded to, add greatly to the sum of human misery. As we know, there are many infirmities that may be inherited, such as epilepsy, chorea, deaf-mutism, and various mental disorders. A person afflicted with any one of these who mates with another similarly affected will under certain circumstances transmit them to the offspring, who will in turn hand them down to succeeding generations. In fact, Karl Pearson[2] has claimed from his study of statistics that 75 per cent. of all deaths are due to inherited diseases. If in the further study of eugenics it can be shown that this percentage is even approximately correct, it ought to arouse physicians, parents, guardians, teachers, and friends to their duties, as such, in warning the public that there is always a greater likelihood that these diseases will be transmitted by such marriages than that they will not, certainly if Mendelian principles are correct. These dangers that Pearson has

*Read in part at the annual meeting of the American Therapeutical Society in Albany, N. Y., May 29, 1914.

pointed out, we have, however, been in the habit of disregarding. As a matter of fact, we are often and truthfully charged with even greater offences against human eugenics, as when we bring unfit infants into the world and afterward use our best efforts to keep them in it. And we increase the numbers of the unfit in proportion as our medical knowledge and skill develop. Unfortunately, too, for human eugenics, in so far as we help in the transmission of physical and mental defects, we will continue to offend so long as legal or moral laws prohibit us from doing otherwise. We are not yet arbiters between life and death.

Take an instance of our misconduct against eugenics: Dwarfism is a family disease; that is, in the ordinary course of nature it would become extinct, but is maintained by the intervention of a Cesarean or other life-saving operation. For under ordinary circumstances mother and child would perish simultaneously. The skilful obstetrician, however, steps in; the dwarf mother's life is saved, perhaps, and in addition another dwarf may be born into the world.

At this point let me briefly take up some of the salient points concerned in the matter of heredity.

First of all, we must realize that heredity, so far as it relates to the transmission of traits in plants and animals, is a matter that is far better understood than is human heredity. Following the line of investigations pursued by Wallace and Darwin, Mendel and others, and which were begun more than half a century ago, natural or haphazard selection for the purposes of propagation in plants and the lower animals gave place long ago to artificial selection, particularly among nurserymen and breeders of horses and cattle. Flowers can now be made to take on new colors, plants new contours and greater vigor; horses by cross-breeding can in a succeeding generation develop increased speed; milch cows can in a similar way be made to generate a progeny that will yield a phenomenal quantity or quality of milk. The marvelous ability shown by our own Burbank in making new species of plants has never, I presume, been excelled, and his work is still being successfuly prosecuted. But we humans very rarely have such results. We cannot control the factors. Nowadays we are seldom given the opportunity to select human mates, certainly not in this progressive country.

"Love is the tyrant of the heart; it darkens reason,
confronts discretion."

Nor could we, if we would, produce a new species of the genus homo, by grafting or any such mechanical means. Having seldom a free hand, and being unable to achieve the results of the nurseryman, because of the limitations of human capacity, human eugenics as applied to our matings has very restricted possibilities.

However, something may be done by us that is eugenetical, for, if we accept the laws of Mendel, we can tell in advance what the expectation will be as to offspring in fit and unfit matings, and to some extent the relative proportion of normal and abnormal under ordinary conditions.

Gregor Johann Mendel was an Austrian monk, and he is credited with having been the first to enunciate the laws of heredity. Versed in physics, mathematics, and the natural sciences, he studied the effects of crossing various sorts of edible peas in his monastery garden. Singularly, he appears not to have been known to Darwin, though his work was done between the years 1857 and 1865. He died without having received recognition for his discoveries, which were not made public until 1900, or sixteen years after his death. His laws or principles may be briefly stated in the following general terms:

1. Every organism, from germ-life upward, contains within it an aggregation of characteristics representing the several elemental traits that have been inherited from a previous generation. Each organism is therefore made up, as it were, of a mosaic of molecular elements. Among these are certain dominating characters, called by Mendel *determinants*.

2. On the other hand, there are also organisms of the same species in which this dominant type is either absent or deficient. This sort of organism, according to Mendel, represents a *recessive* type. It is defective in respect to the elements of the dominant type.

3. If a dominant is crossed with another of the same type, the succeeding generation will all be of the same dominant type.

4. But if one of the dominant type is crossed with another of the same species which has but a single recessive characteristic, the result will be that 25 per cent. of the succeeding generation will be of the recessive type, and 75 per cent. of the dominant type, though not in the same degree. In one the grade of dominance will be marked, but it will be less in the other two.

5. Again, if one of a recessive type mates with another of the same type, all of the succeeding generation will be of the recessive type, that is, defective.

These Mendelian doctrines have been tested with reference to the feeble-minded by Goddard, as to the epileptic by Davenport, and as to insanity by Rosanoff. The latter has further elaborated six possibilities with respect to the inheritance of either a neuropathic or normal constitution in the human being, in general accordance with his interpretation of Mendel's laws.[3 4 5] Thus,

1. If the parents are both neuropathic, all the children will be neuropathic.

2. If one parent is normal, but with a neuropathic taint from one grandparent, and the other parent is neuropathic, half the children will be normal, but capable of transmitting the neuropathic constitution to their progeny, and half will be neuropathic.

3. If one parent is normal and of pure normal ancestry, and the other parent is neuropathic, all the children will be normal, but capable of transmitting the neuropathic constitution to their progeny.

4. If both parents are normal, but each with the neuropathic taint from one grandparent, one-fourth of the children will be normal and not capable of transmitting the neuropathic constitution to their progeny, one-half will be normal but capable of transmitting the neuropathic constitution, and the remaining one-fourth will be neuropathic.

5. If the parents are both normal, one of pure normal ancestry and the other with the neuropathic taint from one grandparent, all the children will be normal, but half of them will not be capable and half will be capable of transmitting the neuropathic constitution to their progeny.

6. Both parents being normal and of pure normal ancestry, all the children will be normal and not capable of transmitting the neuropathic constitution to their progeny.

The following table, which has been copied from a recently published study of heredity in insanity,

based on seventy-two family histories,[5] shows the closeness of correspondence between actual findings and theoretical expectations according to the Mendelian theory:

Types of Mating According to Rosanoff's Six Types	Neuropathic Offspring		Normal Offspring	
	Actual Findings	Theoretical Expectation	Actual Findings	Theoretical Expectation
1	54	64	10	0
2	190	214⅓	239	214⅓
3	0	0	45	45
4	107	80⅔	215	241⅔
5	0	0	77	77
6	0	0	0	0
Totals	351	359	586	578

It will be noted from these tables that there is a remarkable correspondence in figures between the theoretical and actual findings; sufficient to impress the impartial reader that in respect to the neuropathic constitution, at least, transmission from generation to generation is in accordance with the Mendelian laws as here set down.

Rosanoff tells us also that about two-thirds of all the patients admitted to insane asylums have inherited the neuropathic constitution. That the converse is true has been shown in a very striking manner by tracing the descendants of the distinguished theologian, Jonathan Edwards, as given by Walter.

In further confirmation of the application of the Mendelian laws, Rosanoff has tested them by the records of the Kallikak family already alluded to[6] and has found in 502 individuals traced there was a lack of correspondence between the theoretical and actual findings in two instances only. The figures cited should therefore be taken as proof that the Mendelian doctrine of heredity has very strong evidence in its favor. To disprove them one would be called upon to show inaccuracies in the tables themselves, or else that analogous ill or good results sometimes follow good or ill matings.

It is a matter of satisfaction that eugenics has taught us how a defective strain can be gradually minimized by selective matings, at least so far as physical and mental traits are concerned, the rapidity of the elimination naturally depending, *ceteris paribus*, on the excess of normal dominating germ material entering into the matings. Burbank, indeed, is very optimistic in this respect. He says that if he could only carry out in the human species the Mendelian principles, more could be done for it in ten generations than would otherwise be done in a thousand years. The inference therefore is justified that the physical and mental traits of offspring can to a certain extent be determined before birth through artificial selection.

Within comparatively recent years we have been able to isolate the infecting agents of tuberculosis, gonorrhea, and syphilis. We have also found that the gonococcus has a field of activity which is not limited to the genitourinary tract, as was formerly taught, but that it may produce a systemic disease of great danger to life. So, too, the *Treponema pallidum* of syphilis remains a powerful agent for the infection in the third stage of the disease. And it seems as if the degree of infectivity in the venereal diseases, as with alcoholics and drug habitues, is proportionate to the morbidity of the one who transmits the disease. Consequently, it is only reasonable that persons wittingly transmitting the venereal diseases should be amenable to the law. More than this, in extreme instances it is for the common good that such persons be debarred from procreation. There can be no doubt that sterilization laws such as those of Washington, California, Connecticut, New Jersey, Nevada, Indiana, and New York, if designed to prevent propagation by confirmed criminals, idiots, imbeciles, and rapists, indicate progress in the right direction. The validity of such laws has been tested in the State of Washington, where in September, 1912, a decision as to their constitutionality was handed down by the Supreme Court, the court of last resort in this State for such matters.

However, according to a report in one of our daily papers, the Iowa sterilization law passed by the General Assembly, has been declared unconstitutional, null and void, in a decision filed June 24 of this year by Judge Smith McPherson, District Judge of the Southern District of Iowa. The opinion as stated is that "the statute is in violation of the United States Constitution in that it is in effect a bill of attainder, in that there is to be no indictment or trial; that the statute abridges the privileges and that he is denied equal protection of the laws; that he is denied due process of law; that the statute is in conflict with the Iowa constitution in that the statute denies the inalienable right to enjoy life, liberty, and to pursue and obtain safety and happiness; that there is no jury trial awarded him and that the statute provides cruel and unusual punishment."

This decision will naturally effect similar laws in other States, and the writ of temporary injunction applied for by the inmate of the State penitentiary enjoining the members of the board of parole, the warden, and the penitentiary physician from operating on him was granted.

To what extent these laws have been carried out I have not been able to discover. They certainly have met with great opposition within the ranks of both our own and the legal profession. The question is a medicolegal one. Legislation in this matter, to be effective, must appeal to our intelligent judgment; it must be reasonable in a legal sense.

Many of our State legislatures have also passed laws regulating marriage. There are such in Ohio, Washington, Connecticut, Minnesota, Kansas, Utah, New Jersey, North Dakota, and other States, and the public may be counted on to urge further action in States where there are no such laws.

At present such legislation is to a large extent ineffectual, because the contracting parties can easily cross over into adjoining States, or into Canada. Eventually, however, public opinion, the most powerful deterrent in such matters, will be aroused by the evasion of the law and will make its verdict felt in an unmistakable manner.

Unfit marriages are, as I have already intimated, not only a direct outrage on the offspring, but indirectly a crime against society, when as a result of them the unfit are born into the world. It is not a sufficient reason for neglecting such legislation, that the laws made may not adequately protect the community, for the mere fact that some sort of inhibitory legislation is on the statute books will call attention to its importance and the desirability of not infringing it. To make laws in conformity with present knowledge and requirements and then to alter them in the face of new or special conditions, as may be desirable for the public good, is sound legislation.

But we must remember that there should be no overregulation of marriage. Many will hold with McCready[7] (Medical Record, August 23, 1913),

that "many of the individuals to whom we are indebted for whatever is best in art, music, literature, and science have sprung from ancestors which by present-day standards would be judged unfit"; and with Groszmann that "in the worst of families there has been a sprinkling of perfectly normal individuals." These statements should, however, be very carefully weighed.

At all events, there should be no ill-considered, hasty, or impractical legislation. The recent Wisconsin law was very probably opposed by medical practitioners of the State because its medical provisions could not be carried out. The charge for the necessary physician's certificate as to the applicant's freedom from venereal diseases was limited by the law to $3, whereas a full examination for syphilis alone would ordinarily cost $10, and under some circumstances six times that figure, and even then no physician could affirm with absolute certainty that syphilis was absent. A law requiring such certificates will, as in the Wisconsin case, fail of its purpose. But on the whole this incident may have a salutary lesson, even if it merely calls attention to many of our modern laws which often seem to be made to be broken. Anyone who is familiar with such laws will bear me out when I say that they are very apt to be hastily conceived, badly drawn, and often hedged about with so many restrictions that they cannot be enforced.

However, the Supreme Court of Wisconsin has upheld its marriage law by a recent decision. The objections on the part of physicians were met by the extraordinary holding that even if physicians could not prevent unfit marriages owing to the inadequacy of the allotted fees they could at least protect society from the effects of such unions. The legal objections that it established an unconstitutional discrimination by requiring that only men must have a satisfactory record was met by an equally curious holding, that such a classification was permissible.

But notwithstanding such inappropriate legislation, the intention of the court was undoubtedly to make a move in the right direction.

And this statement leads me to say as a corollary that all legislation in medical and sanitary matters should first be passed upon favorably by medical organizations, qualified to act with authority in legislation of this sort.

Such appears to have been the course pursued by our representative in Congress, the Hon. Lathrop Brown, in the matter of the bill introduced by him, already referred to. It may be safely predicted that any such bill introduced into Congress will have little support there, at the present time, unless backed by the medical profession, through its representative bodies. Even if by any chance such a bill should pass and become a law, I believe it would prove inoperable without the concurrence of our profession.

Apropos of legislation on this subject Dr. Charles B. Davenport of the Carnegie Institute of Washington, in charge of the Station for Experimental Evolution at Cold Springs Harbor, L. I., says that most of the so-called eugenic laws are failures.

Holding that the problem of eugenics is only to be solved by gradual processes, he says we are investigating but as yet know very little of the laws governing heredity and feeblemindedness. We have, he says, a mass of information but it is not ready as yet to be put before the public. When that time arrives sensible laws can be passed.

In concluding what I have to say on the transmission of diseases through procreation and the regulation of marriage, I do not pretend that we have all the desirable data at hand to sustain any law of heredity and explain its exceptions. We stand on the threshold of a very difficult task, which will require plenty of intellect and money and special facilities for its elucidation. This much I will say, however; I believe that Mendel's principles or laws of heredity have been established firmly enough to serve as a basis for statutory regulations whose ultimate object will be to prevent certain persons with physical or mental defects being permitted to bring into the world offspring to deteriorate it and to be a sorrow to themselves.

But this is not all. In the evolution of the ideal man or woman, we cannot stop at perfection in physical or mental traits. Eugenics halts at the threshold of life. It goes no further. And yet it is here that the most essential attribute of mankind begins to be formed. This is human character, which develops after birth into what Galton has called "civic worth." It is the result of environment and training from birth up. The infant that is born into the world with a perfect physique and a brilliant intellect will be a defective and may some time or other become a menace to society, unless character is acquired. A Plato, an Aristotle, or a Washington might be born into the world ideal in mind and body, but he would certainly be more dangerous to society than an ordinary man, without the proper development of character. A nation composed of such citizens would have in it the elements of its own destruction. It would die as other nations have done; as Greece did, because the Greeks, with all of their physical beauty and intellectual attainments, lacked an essential—character. *Mens sana in corpore sano* is very desirable, but the ideal citizen should also have what Horace has described as *integer vite scælerisque purus.* Conversely, by superimposing on a physical defective character one of the world's greatest leaders may be developed. We have many examples to prove this. The Apostle Paul was one.

Without being either a psychologist or a neurologist, I will venture to say in conclusion:

1. That while human eugenics is still imperfectly understood, there are certain principles bearing on the transmission of traits by propagation that are tolerably well established.

2. These principles should first of all be popularized, so that the adult portion of society will realize the importance of fit and the dangers of unfit matings. With an aroused public appreciation of these matters, appropriate legislation will sooner or later follow and be made effective.

3. Uniform laws as to the regulation of marriage should be urged in every State, and also laws to prevent the transmission of diseases by diseased persons.

4. While the motto *Salus populi, suprema lex,* is true, legislators should only advocate laws that will accomplish satisfactory results without an unreasonable curtailment of personal liberty.

5. There is urgent need of further researches in the field of eugenics, in order to clear up misapprehensions and so allay criticism as to its civic value. But, as this work would necessarily involve the services of special medical experts, expenditure of large sums of money and unusual facilities, it should be relegated to the States or the general government, which could provide the men, money and opportunities, and accomplish the most at the least

expense. Reports from such sources would serve admirably as bases for the framing of appropriate laws, or for the amendment of those that have proved to be unsatisfactory.

CHRONIC INTESTINAL STASIS.*

BY S. WENDKOS, M.D.,

PHILADELPHIA, PENN.

CHIEF OF MEDICAL CLINIC, OUT-PATIENT DEPARTMENT, MT. SINAI HOSPITAL, PATHOLOGIST TO THE JEWISH CONSUMPTIVE INSTITUTE.

CHRONIC Intestinal Stasis is a new term for its old, and timeworn synonym, constipation, with its attendant toxemia. From time immemorial this condition was held responsible for many ills human nature is heir to. Hence therapeutic measures consisting of castor oil, or enemas, or Carlsbad water, or buttermilk, or certain pills were credited with remarkable cures. In the past, constipated patients were benefited by pills of one kind or another, until the laity caught the trick and ceased going to the doctor for such a minor ailment, and themselves experimented with various pills, such as the ingenuity of the manufacturer could devise, or the druggist could suggest. As they all failed in the end and the doctor had to be consulted, the latter only varied the dose of this or that or other drug compound without any attempt at thorough investigation or even cursory examination.

It is only of late that we really have begun to understand the etiology of intestinal stasis. To this contributed the experimental physiologist, clinician, radiographer, and surgeon. Of the first the European gastroenterologists, Von Noorden, Boas, Strassburger, and most of all Adolph Schmidt, have contributed enormously to our knowledge of the exact physiology and pathology of the alimentary tract. Schmidt, for instance, has devised a test diet for intestinal function. This diet has been standardized and is fixed even as Boas's test breakfast and Riegel's test meal. When this diet is administered for three days, the motility of the intestines can be estimated as correctly as with the *x*-ray, especially when a few grains of carmine are added to the first meal whereby it is colored slightly red. From this can be calculated the time necessarily consumed under ideal dietary conditions. By examining a portion of the feces, it is at once revealed how the stomach, pancreas, liver, and intestines function; that is, whether they contribute their hormones which, acting through the blood stream, excite peristalsis. One can readily see its importance in the study of stasis. The study of every case, when possible, should begin with a functional test meal for the intestines. Schmidt found, for instance, that raw connective tissue is dissolved by the stomach only, that the nuclei of meat fibers are digested only by the pancreatic secretion. He deduced from his extensive studies that constipation is often due to a too thorough absorption of the fluid elements from the feces. He, therefore, suggested the use of agar-agar, a fluid-retaining and therefore bulky substance. The intestines must be properly distended in order that peristalsis may occur. The researches of Starling and Baylis also showed that intestinal stasis is due to a diminution of an internal secretion, which they called hormone, which, when reinjected into the body, causes peristalsis. He isolated this chemical substance largely from the spleen, and this has been used in ileus.

Later came the radiographer and objectively projected the passage of a bismuth or barium test meal, while at the same time taking note of the duration of its passage through the intestines. He was able to show to the naked eye the actual contortions of the intestinal tract and to our frequent amazement disclosed conditions unsuspected by clinical methods —gastroptoses, festooned colon, dilated cecum mobile and sigmoid, kinks, and adhesions.

More recently Sir Arbuthnot Lane has demonstrated what he believes to be the causes of chronic intestinal stasis. I do not wish to dilate on his contribution to our knowledge of this condition as the next speaker will probably deal with it more fully. I only wish, however, to say that surgery's contribution to our newer conception of satsis is indeed epoch making. Just as another surgeon's, Moynihan's contribution concerning duodenal ulcer enabled the clinician to retrace his steps, better to understand its pathology, and consequently treat this important affection more scientifically and more intelligently.

From a rather large experience with cases of stasis in our clinic, I have ranged the patients in several groups. First comes the school boy or girl, pale, prematurely old visaged, complaining of a dull headache, coated tongue, poor appetite; perhaps some palpitation, weakness, and pains in the joints. These always had trouble with their stomachs ever since they were babies. The second class comprises the young mothers, who date their troubles from their first child. They are nervous, losing flesh, with pigmented and blotchy skins, insomniacs. They were always well before the childbirth. The third class includes middle-aged people, who suffer from some concomitant organic disease, as gallstones, chronic appendicitis, pelvic disturbances, hemorrhoidism, etc., with constipation as a main complaint. The fourth class includes the aged and debilitated in whom, through misuse of drugs, the bowels have become almost paretic. It is evident, that a clear history from each and every sufferer from constipation will suggest its own line of treatment. A good history is a *sine qua non* of intelligent treatment. Having obtained this, we are confronted with the following symptomatology. Lane classifies these symptoms as primary and secondary. "The primary symptoms are loss of fat, wasting of the voluntary and involuntary muscles, degenerative changes in the skin associated with alteration in its texture and color. Subnormal temperature, especially in the extremities. The mental condition is one of apathy, stupidity, or misery. This may become exaggerated into a state of melancholia or even apparent imbecility. Headache is a very frequent feature and may render the patient's life unendurable. Rheumatic pains and aches in the muscles and joints, often in the skin, are present.

*Read before Mt. Sinai Clinical Society in a symposium on intestinal stasis.

The thyroid gland wastes. Blood pressure may be raised or depressed. Degenerative changes occur in the breasts in the upper and outer zones and cancer readily develops in this condition.

"The several organs prolapse and alter in shape, partly because of the loss of fat, partly because of the wasting of the muscle fiber. Dyspnea and degenerative changes in the heart muscles occur. The kidneys are liable to become affected by the abnormal strain thrown upon them. The hair of the head loses its color early in life and tends to fall out. The pancreas becomes infected directly by extension from stagnating contents of the duodenum. This results in chronic induration, chronic inflammation, and finally cancer of this organ. In similar manner the ducts of the liver and gall-bladder are infected and gallstones, cholecystitis, and cancer may be produced, besides many acute or chronic diseases of the liver. Those diseases of the eye which are degenerative in origin are produced by and varied with the degree of autointoxication.

"The obvious indirect changes are infection of the gums, causing the condition commonly described as pyorrhea alveolaris, tuberculous infection not produced by direct inoculation. Rheumatoid arthritis. This, like tubercle, cannot develop except in the presence of defective drainage of the gastrointestinal tract. Infection of the genitourinary tract, either directly or indirectly through the blood stream by organisms other than tubercle, producing nephritis, cystitis, pyelitis, endometritis, salpingitis, etc. Changes in the thyroid gland, whether adenomatous tumors, general enlargement of the thyroid, or exophthalmic goiter. Infection of the skin of a pustular nature, Still's disease. Infection of the large intestines by organisms, which produced the several varieties of mucoid and ulcerative colitis. Ulcerative endocarditis."

By pointing out his array of symptoms, Lane wished to impress the profession with the extreme importance of stasis, which to the laity as well as physicians appears of so little significance. To diagnose chronic intestinal stasis there are two courses open to the busy practitioner. First, to refer the patient at once to the radiographer, which to my mind is a deplorable tendency as it may lead to errors of judgment in treatment; secondly, to investigate by clinical and laboratory methods and then check the results by radiography and fluoroscopy; this seems to be ideal. As many of these patients are ambulatory and come to the office where there is no *x*-ray apparatus ready at hand, the question arises, what can we expect from physical examination? There is no doubt to my mind that the physical diagnosis of the abdomen is largely neglected, but when practised as carefully as over the chest or precordium considerable information can be gleaned. A physical examination alone will reveal an enteroptosis a dilated movable cecum, a tender spot at McBurney's point, a corded descending colon. Hayes and Jordan can even determine by physical means a dilated duodenum which they claim is indicative of iliac stasis. The diagnosis, as a rule, is not difficult.

The medical treatment of chronic intestinal stasis must perforce limit itself to cases where there is no clear evidence of definite organic disease, as ulcerations of stomach or duodenum, gall-bladder, or appendiceal disease. These cases should be referred to the surgeon. Again referring to Lane, he defines stasis as follows: "By chronic intestinal stasis I mean that the passage of food along the alimentary canal takes place with such slowness that there is formed an excess of toxic matter especially in the small intestines. Consequently the blood flow pours into the transforming and excretory organs a quantity of poison larger than they can eliminate. From this it results that all the tissues of the body, drenched in this blood rich in poisons, degenerate and offer a diminished resistance to infection. A defective drainage has consequences which are deleterious to the organism in general as well as to the individual tissues of which it is composed."

Having this conception clear in our minds, what can we do medically to reestablish a proper bodily drainage, so as to rid the organism of an excess of toxic substances?

All treatment nowadays must begin with efforts at prevention. We must begin with the school child or even with the baby. Boas speaks of improper bowel training. Many mothers do not know how to train their children at natural defecation. The bowel syringe put into the hands of some mothers has been a curse to many children. Too frequent recourse to it prevents a proper education of the rectal nerve apparatus and so we find the school boy or girl with all the toxic symptoms of stasis due to a dilated sigmoid. The education must begin with strict instruction to visit the toilet at a certain fixed time and that the slightest warning of nature should be peremptorily obeyed. The teacher should be apprised of the fact so as to facilitate the pupils' going out during the school session. Girls, especially, suffer from constipation because of lack of bodily activity, hence the systematic exercises instituted in our school system are highly beneficial to develop the abdominal muscles and diaphragm, which, in turn, influence to a great extent intraabdominal pressure. Dr. Sever demonstrated in a large number of children by means of the *x*-ray a very marked gastroptosis due to improper posture. In some cases the stomach lay in the pelvis. Hence in aggravated cases of stasis, children should be *x*-rayed and abdominal supports applied.

Diet is a most important factor in the restoration of the normal intestinal activities. Immigrant Jewish patients in particular suffer from a lack of fecal residue. The foods they consume are too thoroughly digested, leaving little waste matter, which cannot be propelled through the commodious lumen of the colon. They entirely abstain from vegetable diet. The physician who wishes to instruct Jewish patients in their use must not only be an experienced marketer, but also a trained dietician. I frequently have to write out the names of certain vegetables, explain their use, taste, and smell, and even give recipes for stimulating and appetizing salads. The Italians, on the other hand, consume immense quantities of fresh vegetables, and chronic intestinal stasis is comparatively rare among them, even among their women with large protruding abdomens resulting from frequent childbirths. Important as dietary measures, besides vegetables, are other foods, such as graham and rye breads with butter, pumpernickel, fruit; buttermilk, cider, and beer are useful for their qualities of fermentation. Fats are especially to be recommended in patients who suffer from enteroptosis. Salt stimulates the intestinal movements, therefore foods containing salt are indicated in this condition. Perhaps this is the reason why Jewish patients like herring so much, and others caviar. Sugar, especially milk sugar, has a marked tendency to increase intestinal peristalsis. Cold water taken on an empty stomach,

before breakfast, will stimulate the bowel movements. Patients should be impressed with the necessity of adhering to a strict dietary, specially written out or printed, and urged to persist in it for a long time.

We come now to the second class of cases, namely young mothers. They complain of constipation, headache, flashes of light, cold hands and feet, poor appetite, bad taste in the mouth, and occasionally also loss of weight. I have seen hundreds of these cases. They are suffering from Landau's disease. On examination their abdominal muscles are partially or totally atrophied and diastatic; there is a hollow between the ensiform cartilage and umbilicus, showing even superficially that there is an enteroptosis internally. Sometimes the right kidney can be palpated, thus confirming the diagnosis of intestinal prolapse of a mild degree. These patients are greatly benefited, in addition to a fat diet, by orthopedic supports. Massage and electricity, with a sinusoidal current would be well, but it is a waste of time to suggest it even, as the patients do not feel it is worth while to undergo such expensive treatment. In my experience with dispensary patients of this type, I frequently apply a Rose bandage, made of adhesive plaster, before I advise a regular elastic belt. The application of this is really in the nature of a test for a week or two. If they feel improved by wearing it they are advised to purchase some of the standard bandages.

Those of you who practise obstetrics to any extent must bear in mind the possibility of a beginning enteroptosis following labor and should advise a support as soon as the patient commences to move about.

The cases which in addition to the symptoms of intestinal stasis also show symptoms of organic disease should be treated medically for a reasonable length of time in an endeavor to cure the organic lesion. When this fails operation should be insisted upon as a cure for chronic stasis. The treatment of these patients is best carried out in a hospital. The presence of obstinate constipation with nausea, belching, anorexia, dating back for many years with occasional exacerbations, raises a suspicion of a gastroduodenal ulcer of an atypical kind; or occurring after an attack of colic, suggests a possibility of gallstones or adhesions. Granting that the anatomical basis for chronic stasis may be adhesions anywhere along the intestinal tract and knowing that inflammatory connective tissue is absorbable, why not treat the adhesions medically? Rest in bed, manual applications about the suspected regions, hydrotherapy, iodide of potassium may do a great deal for the patient. I have seen patients operated on for duodenal ulcer and gallstones and nothing was found, except some slight adhesions. Incision and drainage only increase the possibility of adhesions. Boas in a recent article says that the internist was accustomed to think surgically, and it behooves the surgeon now to think medically. Therapeutic measures of a medical nature should be exhausted before the knife is used.

The treatment of the fourth class will be dealt with under the heading of drugs. After all that is said and done, drugs are still the mainstay of medical practice. Other methods are only accessories and may be very essential, but drugs, wisely and discriminately used, are of the greatest help.

In administering drugs for the relief of stasis and its resulting symptoms one must bear in mind clearly the exact condition he is dealing with. Assuming then that the major symptoms are toxic in origin due to an excessive activity of the bacteria, and their action on protein, it stands to reason that the first necessity is to diminish the amount of bacteria in the intestines. No known intestinal antiseptic has yet been found efficacious in overcoming them. Metchnikoff's bacillus has some claim on us for its power to inhibit the growth and activity of intestinal bacteria. After a preliminary purge, I administer a five grain tablet of bacillus bulgaricus t.i.d. to be taken indefinitely. The next use for drugs is to keep up a steady, mild peristaltic action. This can be done only by increasing the natural secretions of the intestines and their adjacent organs, as, for instance, the liver and pancreas. The use of physiological preparations is rational. They stimulate the various organs to renewed function, thus supplying the protective substances against alimentary toxemia and indirectly stimulate peristalsis. In a recent symposium on the same subject we are discussing to-night, Dr. Saundby of England maintained that under physiological conditions the natural protective agencies in the alimentary system are sufficient to protect the body from the dangers of poisons, formed therein or those introduced with the food, provided these are not overwhelming in amount. Such morbid symptoms as arise may well result from a breaking down in the protective machinery, in consequence of functional defects.

Therefore, and from analogy of the thyroid gland, physiological products, such as inspissated oxgall, pancreatic gland extract, enterokinase, secretogen, etc., etc., may be used and should be given a trial. Of the other drugs that stimulate the glands of the intestines cascara is by far the most useful one.

The musculature of the bowels also needs stimulation, hence strychnine, eserine, and sometimes belladonna to relieve a spasmotic condition are useful. In our clinic, treating as we do hundreds of such patients, we have found of the greatest benefit a mixture of aloin, 4 grains; tinctures of nux vomica, physostigmine, and belladonna, of each 1 dram; fluid extract of cascara, 1 ounce. This is administered in 15 to 20 drops and the patient is instructed to vary the dose to his or her needs. The patients rarely get used to it, and when they take it for some time we frequently observe a restoration of natural intestinal function. Not infrequently have we found that after the administration of sodium bromide the bowels commenced to act naturally. The same was observed when giving a tonic of hypophosphites. The general nervous system must not be overlooked while we are endeavoring to influence the gastrointestinal tract.

The two most common seats of stasis are the cecum and the sigmoid. Where there exists a cecal stasis, agar-agar, dram 1-3, taken t.i.d., or with the breakfast food, has been found to be very efficacious. In stasis of the sigmoid, the main attack is to be centered on increasing the sensitiveness of the rectal mucosa. In this connection enemas have been most serviceable. Also electricity is important. Liquid paraffin and Russian mineral oil have been suggested. My patients disliked it and refused to take more than one dose.

This line of treatment cannot always be applied to dispensary or office patients, but I have applied it to some of my private patients, and not all of them got well. In those that did not recover, upon repeated examination I began to suspect chronic

appendicitis or latent gallstone disease. Several patients were operated upon and remained well after that. How much surgery can do for chronic intestinal stasis with or without bands and adhesions, is still a problem for the surgeon to solve.

1527 North Franklin Street.

PARENTERAL NUTRITION AND ITS SURGICAL APPLICATION;

WITH SPECIAL REFERENCE TO THE USE OF GLUCOSE SOLUTIONS IN POSTOPERATIVE SHOCK.

By A. C. Burnham, M.D.,

New York.

In the treatment of surgical shock, just as in the treatment of traumatic shock, the indications are to adopt those measures which may assist in carrying the patient through a crisis lasting from a few hours to several days. During this time the entire organism is subjected to a severe strain for which it is often poorly prepared. Surgical shock, in contradistinction to the traumatic variety, often finds the patient in bad condition, due usually to a combination of three causes. These are: First, the pre-existing disease; second, the nervous strain preceding the operation; and finally, the period of enforced starvation before the anesthetic. To these are added, during the course of the operation, the surgical trauma and the toxicity of the anesthetic.

All these causes of shock are recognized, and an attempt is made to overcome as many of these factors as possible, without jeopardizing the lives of the patients or causing them serious bodily discomfort. The search for a safer anesthetic is constant. Crile[1] has taught us that much can be done to reduce the nervous stress, both before and during the operation, and the attempt is always made to put the patient in good physical condition before undertaking any operation of choice. The nutrition of the patient, however, during this period of intense cellular and nervous activity, has been neglected. This is especially true in those operations of necessity, where the condition of the patient is such that immediate operation is desirable, and there is often a state of malnutrition, due to the effect of the disease on the alimentary canal.

It is not uncommon to see, even in patients who are well able to digest and assimilate food, a period of enforced starvation preceding the operation, which may be drawn out to eighteen hours or even longer. If we add to this the period after the anesthetic, during which the patient is unable to take nourishment, we see that in many cases otherwise doing well the period of starvation may easily extend to forty-eight or seventy-two hours. This is probably of little import in a healthy adult who has reserve stores of nutritives scattered throughout the body, but in the patient already weakened by infection and defective assimilation this becomes a matter of great consequence, and, conceding the kinetic theory of Crile, the combined injury to the nerve cells may be so great that they are not able to regenerate; the patient, no longer able to respond to the stimuli, succumbs to the infection.

The injury caused by starvation theoretically acts in a number of ways to cause injury to the central nervous system. First, it deprives the cells of certain elements which are derived from the food, and which are carried to them by the blood stream (whether the food is absorbed directly by the nerve cells or is first changed in character at some other point is not important, the ultimate result being the same); second, it adds to acidity of the organism, which in itself (according to Crile) acts as a direct injury to the cells of the nervous system. (The presence of an acid intoxication following operation is recognized as occurring after more than half of all operations); third, it deprives the blood of chemical substances, which act as detoxicating agents on absorbed poisons. The conjugation of sulphates and glycuronates is the best known example of this action. There are probably other injuries to the nerve cells which may be directly or indirectly traced to starvation, but the above are the ones which are well recognized and serve to emphasize the points which I am most anxious to bring out.

It is desirable then, especially in that class of patients who are already poorly nourished, to take some measures to overcome the lack of food material in the circulating blood. Secretan[2] has recognized this and has emphasized the importance of food given shortly before operation, in the prevention of surgical shock. He asserts that it is usually safe to give some easily digested food from two to four hours before operation. There is, however, a large class of operations which do not permit of feeding by mouth for a considerable period before or after operation. These are in general the operations on the gastro-intestinal canal, and other abdominal operations, and it is especially these cases I am discussing. However, much that is true of the laparotomies is likewise just as true in other operations where shock is apt to be severe. The elimination of this particular element in the causation of shock is to be found in parenteral nutrition.

The term "parenteral nutrition" was coined about ten years ago to indicate any form of nutrition which takes place without the intervention of the intestinal canal. That is, practically, direct feeding of the body cells by substances introduced into the blood stream. There have been many recent advances in our knowledge of this subject, and it is the desire to present the more important experimental facts and to indicate their clinical significance that has led to the preparation of this paper. In parenteral nutrition to a much greater extent than in oral feeding it is necessary to determine what type of food is most adaptable to the organism and in what form this food should be given.

Proteins.—For a long time it has been firmly believed that protein substances injected directly into the blood stream act as cell poisons. This is, in the case of some proteins, undoubtedly true, yet one has only to point to the many successful transfusions of human blood and the injections of therapeutic serums to indicate the limitations of this statement. However, it was not until recently believed possible to maintain an animal in nitrogenous equilibrium solely by means of subcutaneous injection of nitrogenous material. While this subject is in the experimental stage, and is not applicable at this time to the human organism, yet the work done has proved so interesting, and its results may be so far-reaching that it may be profitably described in some detail. Henriques and Anderson[3] are responsible for our present conception of protein parenteral nutrition. They have recently published results of experiments, in the course of which animals were kept in nitrogen equilibrium and gained weight for a period during which they were fed entirely by means of nutrients injected directly into the blood stream. They reasoned that, contrary to the gen-

eral belief, the end products of protein digestion (the animo-acids) were not built into more complex proteins during their passage through the wall of the intestines, but that the change took place at some other point, and that animo-acids could be synthesized in the same manner when injected directly into the blood stream. This hypothesis was based on the work of Folin and Denis, who proved the presence of animo-acids in the blood after the injection of large amounts of protein food.

Henriques and Anderson injected a solution consisting of muscle protein (previously subjected to the action of trypsin and erepsin) together with sodium acetate, glucose, and inorganic salts. During a period of eighteen days, in which nothing was given by mouth, the animal not only remained in nitrogen equilibrium but actually gained weight. This experiment proved that both sugar and acetate can be burned when injected directly into the blood stream, and that the nitrogen so given is sufficient to supply the body needs over a considerable period of time. Goats and dogs were used in the experiments and the solution was given through a permanent canula introduced into the jugular vein. The fluid was slowly introduced during the entire twenty-four hours. Beef and veal were the source of the nitrogen, and the caloric needs were supplied by glucose and sodium acetate, in the proportions of 10 grams and 38 grams to the liter. Finally a mixture of chlorides was added, equivalent to about 1 per cent. This solution varied slightly, the glucose and sodium acetate being decreased as the nitrogenous content was increased. Part of this sugar (16 to 40 grams) was excreted by the kidneys, and there was a slight increase in the ammonia nitrogen in the urine. About 80 per cent. of the nitrogen was excreted as urea. From these experiments it must be accepted as proved that the end products of protein metabolism can be built up again without having to pass through the intestinal wall. Moreover, they give very definite proof of the ability of the animal body to assimilate and burn up glucose when injected directly into the blood stream.

I have never known of an attempt to nourish man by means of the injection of nitrogenous materials. This may be accomplished in the near future, but it is a problem of great complexity and should be approached only with extreme caution.

Fats.—In 1895 von Leube[4] injected butter fat into a dog previously brought into nitrogenous equilibrium, and noticed a gain in weight during a period of six weeks. During this time 1400 grams of fat were injected. From his experiments he concluded that butter fat could be stored in the animal tissues, and later utilized as food. Winternitz working with olive oil decided that fats were absorbed too slowly to be of any value as a food. Henderson and Crofutt[5] also decided that in cases of malnutrition in dogs fats were absorbed too slowly to be of value. Mills[6] in a more recent report found that in a patient with pulmonary tuberculosis certain fats could be injected without causing irritation or other bad effects, and that during starvation they were absorbed in sufficient quantities to furnish one-half to two-thirds of the total caloric requirements. He recommends oil of lard, cocoanut oil, peanut oil, etc., made into an emulsion with egg lecithin, as being the least irritating and most satisfactory form in which oils may be injected. It is possible that in cases of malnutrition, due to the mechanical inability to assimiliate food, some such method may find application.

Sugar.—Of all the carbohydrates the sugars are the ones most easily adapted to parenteral nutrition, and this discussion will be confined entirely to the use of sugar in some form. In every case glucose is the sugar used, and, unless otherwise stated, when sugar is mentioned glucose is the form of sugar referred to. Lactose, maltose, and saccharose are utilized only to a very slight extent and should not be used in acute or subacute conditions. The use of sugar intravenously is of comparatively recent origin. Bonny[7] in an article on the use of glucose solutions in acidosis, says that Barlow recommended glucose solutions by infusion as early as 1895. More recently Kausch[8] and Berends[9] have recommended glucose in surgical conditions. This work was apparently original with Kausch, although sugar has probably been so used before. He gives the sugar subcutaneously in from 2 to 5 per cent. solutions, and intravenously in higher concentration, usually 5 to 7 per cent.

Is sugar utilized by the body when introduced directly into the blood stream? In the opinion of the majority of clinicians who have used this method of treatment, there can be no doubt that the food thus given is of extreme importance in the nutrition of the patient. Patients look and feel better, and seem to have more resistance than when the nourishment is dependent entirely upon rectal feeding. An appreciable amount of food may be given by this means during the course of twenty-four hours, often as high as 100 to 120 grams of glucose can be given, representing approximately 400 to 500 calories. In addition to clinical evidence, laboratory results favor the hypothesis that glucose solutions given hypodermically are utilized in the same manner, and practically to the same extent, as are the same solutions when given by mouth. In the first place the sugar disappears in the human body. Thannhauser and Pfitzer found that in the normal individual the injection of 35 grams of sugar during a period of fifteen minutes causes an immediate increase of the sugar in the blood from .08 per cent. to about double that amount. In spite of this the urine contained only small amounts of sugar. In patients under treatment it is rare to find more than 2 to 5 per cent. of the injected sugar in the urine. If the sugar disappears there are only two possible explanations for its disappearance; either it is burned up in the body or it is built up into higher compounds. Cohnheim,[10] and Gigon and Massini[11] have brought forth experimental data tending to show that isolated muscles, and some other tissues, contain an enzyme which permits them to utilize sugar directly, while Levine and Meyer[12] believe that the latter explanation of the disappearance of sugar when mixed with muscle is the more probable one. However, the experiments of Henriques and Anderson, already cited, prove conclusively that, in a living dog, injected sugar solutions are burned up and serve as sources of energy and heat.

Even more striking are the calorimetric experiments of Vezar and von Fejer[13], who demonstrated that the respiratory quotient rose in the same manner after the injection of glucose as after its administration per os. They injected 134.5 c.c. of a 10 per cent. solution into a normal dog and found that the respiratory quotient rose from .736 before the injection to .890 immediately after it. This proves that glucose is oxidized when introduced into the circulation of a normal dog, and reasoning by analogy, a similar oxidation occurs in man.

Glucose, then, fulfills the requirements of a soluble nutritive that, in an emergency, can be injected into the blood stream furnishing at least a portion of the necessary caloric needs of the human organism. Moreover, sugar solutions have other indications, and this is especially true in the condition of surgical shock. They act mechanically, filling up the blood vessels and thus acting as a stimulant to the heart; they decrease acidosis, and thus put the organism in a better condition to recover from injury; they act on certain toxins to form conjugate glycuronates which are nontoxic; and, it is possible, if not probable, that they act as a direct tissue food to the cells of the heart muscle and of the central nervous system, thus enabling them to regenerate more quickly after injury. Kuhn[14] believes that sugar solution acts as a prophylactic against thrombosis, and that the bactericidal

Effect of glucose on the respiratory quotient in a normal dog (134.5 cc of 10 per cent. glucose solution by infusion between 12.10 and 12.50). From Vezar and Fejer.

properties of the blood are increased when the blood sugar is increased. Bainbridge at the New York Polyclinic gives glucose by hypodermoclysis during every severe abdominal operation, with excellent clinical results. Crile, in a personal communication, says that a solution of glucose is frequently given intravenously at the Lakeside Hospital in Cleveland. Personally I have given glucose to a large number of patients and have never seen a bad result. The pain is no worse than after saline; sloughing does not occur, and the clinical result is immeasurably better than when saline solutions are used.

For practical purposes 4½ per cent. solution of glucose in distilled water is an isotonic solution. If the glucose is added to saline or sodium carbonate it is necessary to decrease the strength of the sugar solution to correspond to the increase of the other constituents. However, if given slowly, a 5 per cent. glucose and ½ per cent. sodium carbonate solution, although hypertonic, may be given with perfect safety.

Conclusions.—(1) Parenteral nutrition, although theoretically possible, has not as yet reached that stage of development which will permit of the total nourishment of the individual over even a short period of time. (2) Glucose solutions may be injected into the blood stream in sufficient quantities to furnish for short periods a large portion of the carbohydrate requirement. (3) Both the clinical results and experimental data available indicate a more general use of glucose solutions during and immediately following all those operations in which there is apt to be considerable postoperative shock, or in which postoperative feeding by mouth is difficult or impossible.

WHY YELLOW FEVER IS ENDEMIC IN THE TROPICAL AND ATLANTIC REGION.

By G. DELGADO PALACIOS, M.D.,

NEW YORK.

PROFESSOR OF PHYSIOLOGICAL CHEMISTRY AT THE UNIVERSITY OF CARACAS (VENEZUELA).

NOTWITHSTANDING the researches of the American, French, and Portuguese Commissions for the study of yellow fever, and the no less important investigations of Otto, R. O. Neumann, Finlay, Reed, Carrol, Agramonte, Ribas, Lutz, Marchoux, Salimbeni, and Simond, carried out on man, the reason for the endemicity of yellow fever is still unknown.[1] Even supposing that it should be possible to demonstrate that this fever is produced by a microorganism, perhaps of ultramicroscopic nature, or any other parasite capable of developing in the body of a stegomyia and of being transmitted through this mosquito, yet the problem of the endemicity of yellow fever would still be unsolved. The presence of *Stegomyia fasciata* in a given locality does not explain the existence of this endemic malady, because many localities in the tropical and sub-tropical zone are known, where the *Stegomyia fasciata* exists, and yet cases of yellow fever are not observed.[2] The three necessary conditions to the production of a great outburst of yellow fever are: the presence of the first case (containing the active yellow fever germ), the conveyers (mosquitos), and the favorable climatic conditions. The yellow fever germ, whatever its nature may be, belongs to the general flora or fauna of the Atlantic and American tropical region, in the same way as certain vegetable and animal species, for example, the *Coccoloba uvifera* or the *Cathartes atratus*, which are macroscopic organisms, belong exclusively to the same region. The experimental investigations I have carried out in Caracas, Venezuela, tend to explain the endemicity of the malady, that is to say, the climatic conditions necessary to the production of yellow fever and to its rapid propagation as an epidemic outburst when repressive sanitary measures are not employed.

These favorable climatic conditions for the production of the disease, as it may readily be imagined, do not confine themselves to the physical and meteorological influences supposed necessary for the propagation of the yellow fever germ. For the

production of a severe case of yellow fever, to its complete development and fatal termination, that is to say, to the entire pathogenesis of the disease, the presence of a specific substance of intestinal origin is indispensable. This substance, which I have called cholerythrogen, is produced in the intestine of the great majority of people who live in the tropical and Atlantic region where yellow fever is endemic. It is to be found in the feces and urine of many apparently normal persons, I mean to say especially in the apyretic state. This substance belongs to the chromogen class, yielding by acid hydrolysis a purple coloring matter, cholerythrin, which must be considered in this region as the corresponding pigment of the uroerythrin of the temperate zone. The cholerythrogen associates itself with the urobilinogen and the lime to form a granular concretion, similar to the ordinary intestinal sand, which I have called fecal carcoma on account of its resemblance to the dust made by the wood-louse. This special intestinal sand, which is easy to detect, is to be found in almost every specimen of human feces of the Atlantic and tropical region; and while certain feces contain the fecal carcoma in little quantity, even only in traces, it may be extracted from others in amount up to 4 or 5 grams in 24 hours.

I have made a special study of the fecal carcoma and of the cholerythrogen it contains. I cannot describe here all the investigations and experiments I have performed to discover its physical and chemical properties, its spectroscopic appearances, its quantities in the urine, its bacterial origin, and finally the functions it plays in tropical pathology. Five chapters of a book I have published are devoted to this important subject.[3]

Here I can refer only to some characteristic properties which cholerythrogen presents and which justify considering it as a specific substance, not yet described. It exhibits the phenomenon of *red oxidation*, that is to say it develops an intense carmine color when it is heated for a short time with a 5 per cent. watery solution of caustic soda in the presence of air. Oxygen is indispensable to the production of the coloring matter, and the phenomenon itself is so singular and so brilliant that this reaction makes the cholerythrogen an unique substance in physiological chemistry. This reaction enables the substance to be identified with ease, particularly when it appears as granules deposited in the tissues. Hydrolysis with hydrochloric acid makes the cholerythrogen yield a purple coloring matter, cholerythrin, similar to the uroerythrin of the temperate zone, and as specific as this, with its characteristic and spectroscopic properties. Similarly to uroerythrin, ammonia and alkaline carbonates make it turn successively blue, green, and yellow; later this last color becomes yellowish brown by oxidation. This substance presents, however, only one spectroscopic absorption band, while uroerythrin gives rise to two. It is very interesting to note at this time, on account of its great biological bearing, that in many years of experience I have never found uroerythrin in the urine of the tropical region referred to.

The substance I have already described with the name of cholerythrogen plays an important part in the pathogeny of yellow fever. When histological examination of the kidney, liver, and spleen is made in a fatal case of yellow fever, it is easy to detect in the organs that a great number of microscopic granules infiltrate the tissues, even in the interior of the cells themselves. The microscopic aspect of the specimens presented to the Venezuelan Academy of Medicine gives the impression that a true overflow of pigmentary granules has inundated the tissues. These facts have been established by two Venezuelan physicians: J. G. Hernandez, professor of histology, and F. Guevara Rojas, professor of pathological anatomy at the University of Caracas.[4] It is exclusively in yellow fever that this invasion of pigmentary granules and the fatal anuria appear associated to such a degree as to demonstrate that there is some causal relationship between the two phenomena; especially if it is remembered that there always exists an intense albuminous degeneration of the epithelium which goes on to obstruct the lumen of the renal tubules. After a series of concordant and differentiating reactions I have established the fact that these pigmentary granules are not composed of melanin as it was supposed at the beginning, but of true cholerythrogen. Therefore, the assistance of a substance of intestinal origin in the production of yellow fever in its most dreadful manifestations must be considered as an established fact.

This particular substance, produced in the intestine by the activity of specific bacteria which grow in the tropical and Atlantic region, intimately but not exclusively related to yellow fever, must be considered as a climatic substance, that is to say, a substance foreign to the human organism and to the activity of its cells, otherwise it ought to be found in any locality of the world.

Reasoning along these lines, uroerythrin must also be considered as a climatic substance, that is to say, a substance produced by certain bacteria which are restricted to the temperate zone and therefore independent of the human body, because there are certain regions of the earth where it is not found.

This conception of climatic substances, thus established, is of great importance for the general biology, from a theoretical point of view, and is also of practical interest in medicine. The extreme complexity of biological phenomena makes scientific judgment more critical in physiological or pathological chemistry when a fact must be definitively established. To prove this assertion it will suffice to state that to establish the exclusively intestinal origin of the urinary indoxyl more than one hundred experimental contributions and memoirs have been necessary, and even to-day some points related to this question remain in darkness.

It is a fact that uroerythrin increases remarkably in the urine after prolonged muscular exercise and strong sweats, in rheumatism, heart and pulmonary affections, digestive troubles, etc. It would require a great deal of experimental work to establish the exclusively intestinal origin of uroerythrin under such circumstances as all these are; but the fact that uroerythrin is a climatic substance, that is to say, that there are some localities in the world where this urinary pigment is entirely absent and is replaced by another one of equivalent value, makes the solution of the question a very simple one.

The medical interest of this fact is of no less importance. If it can be admitted that a climatic substance is endowed with certain toxic or pathogenic power as it has been said, and as the matter has been established for other substances of intestinal origin (paracresol or indol by Metchnikoff[5]),

the role that fecal absorption of climatic substances plays in the special pathology of certain localities becomes of the utmost importance, and explains the production and non-existence of maladies in certain regions and also the variations in their symptoms. As an example of the significance of this subject in relation to the knowledge of the nature of certain maladies I will refer the absence of rachitis in certain provinces of Japan,[6] its absence in all the territory of Venezuela, and also the absence of coma diabeticum in this last country. The constant absence of diacetic acid in the urine of diabetics explains sufficiently the absence of the fatal coma referred to. The whole anomaly may be fundamentally related to the absence of certain bacteria in the intestinal flora, specially the butyric acid germ.

The relations between the chemical and bacterial phenomena in the intestinal tract on one side, and the pathological variations referred to on the other, suggest an entirely new method of investigation, which the author has employed with advantage in establishing the pathogeny of certain maladies, like that of diabetes, whose nature remains unknown at present.

In the case of yellow fever it is not possible to establish what relation exists between the climatic substance of bacterial origin and *Stegomyia fasciata*, but the fact that this mosquito grows near human habitations and the observation of Reed whose success was greatest when he added fecal matter to his breeding jars are very suggestive.

221 WEST SIXTEENTH STREET.

THE INTERRELATION OF THE EX-INTERN AND THE HOSPITAL.

BY LEGRAND KERR, M.D.,

BROOKLYN, N. Y.

VISITING PEDIATRIST, METHODIST EPISCOPAL AND THE BUSHWICK HOSPITALS; CONSULTING PEDIATRIST, WILLIAMSBURGH, SWEDISH AND ROCKAWAY BEACH HOSPITALS AND THE INDUSTRIAL HOME FOR CHILDREN.

IN every realm of human activity and thought it is common to find that rapid advancement is made at the cost of known values. With the substitution of the new for the old, of the up-to-date for the out-of-date, there comes the relinquishing of things that were useful and had valued associations. And occasionally things are laid aside which make us stop and question for the moment as to whether the new is really an advancement. Coincident with the demands of higher education in medicine and more practical knowledge of its details, hospital internship became a desirable though not an essential step in the physician's advancement.

With the enlarging possibility of an internship in view, the need of the instruction and influence of the preceptor in medicine became supposedly less marked and more perfunctory. Not that the need was less, but the attitude of the student became less dependent and more intolerable. Then with the lengthening of the course of study and the more stringent requirements for admission, there occurred the gradual passing out of that most valued factor in medical education. In medicine, the study of men necessarily precedes the study of the scientific application of modern methods in diseases and the opportunity formerly offered to students of seeing patients with their preceptor and observing the solution of the problems thus met was a valuable preliminary training. The relation of the physician to his brethren, the principles of professional etiquette, the duty of the doctor to the public, and the way truly to serve were all early inculcated into the mind of the young student and became a part of his life and study. The graduate of to-day lacks in this instruction; the personal side of the physician's art is to him an unexplored field. Even internship in a hospital has not proven a satisfactory substitute because the relation of the intern to the hospital and the hospital to the intern has been more material than personal; more necessitous than mutually helpful.

Before we can deal with the ex-intern we must of necessity deal with the intern, and what are the facts? The appointment of an intern is usually an arrangement of expressed and implied contract. There are certain particulars of the agreement which are averred and mutually agreed upon and this is the express contract. But there are other particulars which may arise because of the relations of the parties and which may be brought into existence without previous knowledge or volition and by implication create an agreement which constitutes the implied contract.

Practically all hospitals require of an intern unusual skill, unusual character, and one or more of the best years of his life. That he is required to possess unusual skill is proven by the scheme of competitive examinations which are held to determine that point. As to his character, requirement is practically always made that certificates of such be filed with his application for examination. By merely accepting the position offered, the applicant impliedly contracts with the hospital that he has such skill, science, and information as will enable him judiciously and properly to perform the duties of that position. But while this unusual demand is made upon the applicant and there exists his implied contract of capability to meet the unusual conditions, there should be no lowering of the standard. Any change must be in the line of greater restriction, and should mean real advancement.

The examination of the applicant should be more personal; it is not sufficient that he prove himself a trained scientist. The influence of the hospital while largely medical is not wholly so and its staff should be qualified in those other characteristics which further the influence which is not strictly medical. This is partly met by the usual custom of the examining board marking a man's fitness. But the method is all wrong. Doctors are not adequately equipped by training to "size up" a candidate. One or more good members of the appointing board, that is, men trained and skilled in the estimation of a man's worth for a place are of more real service than an indefinite number of doctors.

And if this suggestion was really acted upon in co-operation with the examining board, there would be a lessened number of men classed by the attendings as "unfit for further service" at the end of their internship; a serious situation for any young man.

In marking a candidate's fitness, the individual members of the hospital staff are very likely to be influenced by the standing of the applicant in the technical examination, his alma mater, and the importunities of his friends. Therefore the marking of the candidate's fitness by the medical staff is often unsatisfactory and not for the best interests of all concerned. A more nearly perfect scheme and one that is at least worthy of an extended trial would be an arrangement between the board of directors or managers and the medical colleges whereby the faculty of the college recommends to the hospital at stated intervals a senior for the position. Such an arrangement at once does away with competitive examinations which are admittedly unsatisfactory and brings to the hospital a man who has proven his worth not alone in technical knowledge, but in real fitness and has done this over a long period of observation. The college would be placed upon its mettle to recommend the best of its men and the acceptance of such recommendation by the hospital would result in placing the incumbent upon his mettle to maintain the honor and standing of his college. The working out of the details of this arrangement would remain an individual problem for each hospital, but it immediately does away with many of the objections to the present system and adds other distinct advantages.

The benign influences of the modern hospital flow in many channels to the community, many of them being unrecognized and unappreciated by the bulk of the public. They are accepted rather as "matters of course" than as influences which should be fostered, encouraged, and given adequate moral, public-spirited, and financial support.

Although the public does not recognize this, its own education in the great principles of charity has been largely through the ministrations of the hospitals and much of the development of other agencies of public relief has been inspired by the unselfish work of the hospital. It must be apparent that the modern hospital is the center of that which is highest and best in modern medicine and to keep it so lays a heavy duty upon those who shoulder the responsibility. But no matter how modernly equipped or how able its staff, the hospital does not fully measure up to its responsibilities until it becomes a center of medical instruction also. Its duty is educational as well as charitable; its opportunity is to prevent and limit disease as well as to cure it. As such instruction must come through the staff, it becomes the duty of the management to impress upon the attendings the necessity and value of such instruction to the interns and outside physicians and to provide such means as would further instruction. Fortunately, some institutions have been sufficiently impressed with the value of this branch of service to enlarge it to include physicians not connected with the hospital in any manner. The writer realizes that in a large proportion of instances the young intern feels the importance of his position and the superiority of his knowledge, but, on the other hand, how is he to "find himself" if his bedside instruction consists merely of witnessing operations and being made responsible for the carrying out of "orders" which are given without explanation or reason. The intern is there to learn and between him and his attending there should be cooperation in instruction. It should be his privilege to bring forth his "why" without rebuff and at the same time it is his duty to accept the explanation without immediate or remote criticism because the methods of medical workers differ and it is only by the assimilation of these differences that he can produce a new product stamped with his individuality. A "one-man man" is unfortunate in medicine. Too often a physician's library is made up of one authority in each subject and his opinions are based upon these; too often an intern's individuality is warped at the beginning of his medical career by his ready acceptance of one-man teaching. There are many factors in the ever-increasing difficulty of securing sufficient good candidates for hospital internship, but not the least is the inadequacy of medical teaching. This is not so forcibly true of the surgical side because much can be learned from watching or assisting in a surgical procedure. But on the medical side more than the surgical it is not so much the doing, but the reason for the doing that counts in the instruction of the intern and the attending should realize this. With adequate instruction insured to the intern, candidates would be more numerous because the problem would be partly, but not wholly, solved. The economic factor, the necessity of paying interns, is becoming more and more insistent. How are these educational and other benign influences fostered and spread to the community? Largely through the physicians who also serve the community. Any hospital, every hospital needs the good will of all physicians because through this channel most of its influence flows to the public. And any particular hospital is in special need of the good will of its ex-interns, because their present or former relationship to the institution makes their ill-will weighty and even their neutrality damaging.

Therefore those things which tend to bind the ex-intern to the hospital, to keep alive his interest, and secure his enthusiastic support, help the institution and spread its influence. The ready acceptance of an intern's end of service as a termination of the hospital's interest in him is wrong in principle and damaging in its results. The hospital should be the center of the activities of all of its ex-interns. Every man who has served his time in the institution and is big with possibilities or ripe with accomplishments should be made to feel that the hospital in which he served his internship is the place in which his work may be carried on. But what of the man who has not yet shown his possibilities; the man as yet less brilliant, less forcible? The hospital owes a duty to him just as truly as to his more successful brother. Once having served the institution according to its unusual demands upon him, he should be taken care of by that institution unless he has shown his inability to measure up to modern hospital standards.

The out-patient department is the opportunity for the recognition of satisfactory service within the hospital as an intern. Every man should be given an opportunity in some department for which he may be best fitted, it being clearly understood that good work performed will surely bring its reward of advancement in the out-patient department and eventually within the hospital. We may theorize about it as we please, the bulk of the men who

work in dispensaries do not do so from wholly unselfish motives; they expect to get something out of it as well as putting something into it. Make the reward of good work sure advancement and we secure better service in the department and the development of men sufficiently skilled to fill positions within the hospital later. This means a closer relationship between the out-patient physicians, and those on the hospital staff because if the former after a period of internship are placed in the dispensary and by their work prove themselves capable of advancement, they again become the close associates of the latter.

Those who have the appointing power in a modern hospital have a large responsibility to the institution which they serve and that responsibility should be paramount. But closely allied with this is the responsibility to the ex-intern. What are you going to do with him? Is the completion of his term of service to mark the end of what may have been and certainly should have been a close relationship between the appointing power and the appointee or is that relationship to be continued in other channels? Responsibility to the intern is not terminated by the close of his term of service. There is an obligation of the strong to the weak. The young intern is just at the threshold of his medical career; he is beginning his success or his failure; he needs the advice and help of strong men whether he recognizes it or not. Is he to be denied that advice and the helpfulness which he has a right to expect without begging from those who have accepted his best for a year or more? When the writer tells you that a very large proportion of medical graduates are not in the active practice of their profession at the end of five years from graduation, it will emphasize the fact that medical failures are as real as business ones. The writer would not be misunderstood as advocating the indiscriminate placing of the ex-intern, but given men of equal ability for a position the ex-intern should be favored. But as the interests of the institution are paramount, he must be the equal in ability to all available outsiders. But I do stand for the principle that when a man has once served the hospital it becomes the privilege and duty of the appointing power to guide and help him and make him feel that there is some place in the institution's activities that he can fill if he has demonstrated his worth while in the hospital. One institution which I have the honor to serve, the Methodist Hospital, has through its present superintendent, Dr. Kavanagh, accorded to all of its ex-interns the privileges of the operating room and the private rooms. This is an advance along right lines. Previously, an ex-intern of the institution enjoyed no more privileges than an outsider.

It is an evidence of the tendency of the times toward helpfulness and the demand for efficiency that business concerns of large interests are placing men in other departments when they apparently prove inefficient in one, instead of discharging them. In other words it is becoming more and more the custom to "try a man out" and give him a chance at least to "make good." Because of the character of the service, of the unusual qualities of the man and the very close relationship which he has had toward the institution over an extended period, the ex-intern should not only be allowed the opportunity to prove his worth, but every encouragement should be given him to "find himself" by the hospital that he has served. Too often as intern he has come into relationship with the management of the hospital only when some rule has been broken or there has occurred some infraction of the regulations in the service to which he is then assigned. This is so common a situation that in talking with a large number of men in various hospitals, it is very evident that the men look upon their relationship with the management as one of discipline only and do not presume to look for that helpfulness and interest that is rightfully theirs.

It is an excuse, but no reason to claim that the ex-intern in the first place sought the position; he did, of course, but he was forced to it by the conditions which surround the practice of his profession to-day, and although he applied he was in no manner certain of appointment until after he had met the conditions imposed by the hospital. Let me ask this question: How often do those who appoint know the appointee? In most instances, the man is unknown except through the inadequate and meager information which is brought indirectly. That can be excused if the hospital is being managed as a matter of business and nothing else, but if there is the strong desire and purpose to make it a big institution, not big in size or financial strength alone, but big with human sympathy for the sick and disabled; big with possibilities for human helpfulness, then there must be more personal contact between those who govern, and those who serve.

Even a most cursory review of the relations of the intern and ex-intern to the hospital reveals some well defined needs. First and foremost, greater stress should be laid upon results. A large part of the duty of the intern and the opportunity of the ex-intern in the institution is now perfunctory. It is uninspired work; there are few enthusiasms and because of the methods pursued there are few real aspirations. In most instances the institution has placed the man because there is work to be done and no further interest centers about his work if it remains tolerably satisfactory. And meanwhile the man accepts his position as a necessary or desirable step toward his medical progress. Such an arrangement being cut and dried lacks in the vitality that makes for real progress and full efficiency. Another need is a larger freedom to individuality. It is not sufficient to equip our men with technical knowledge, but with such advancement should come the acquisition of a larger personality. To secure the best results he needs imagination and inspiration and these require individual freedom for their continued growth. All men differ and we should strive to get away from the usual method of endeavoring to have them all fit a common mould of our own fashioning. Then when there is a realization of the full possibilities of the hospital and the benign influences which it spreads through the community, there will come a closer contact between the heads of the several departments and all other branches of the institutions so that the younger men will be given every opportunity to study cases and observe the methods of individual workers in different fields.

How these and allied needs will be met is an individual problem for each institution to work out. That they will be met is certain, for we cannot disregard the tendency of the times. It is simply a question as to which board of directors or managers will recognize the needs sufficiently to seek their solution in co-operation with their medical staff and thus become pioneers in a readjustment

which will immediately benefit that portion of the community which the hospital helps and the staff that serves. This would mean more work for the younger men, but they would measure up to it; it is not hard work that breaks their spirit early in their careers, but hard work without the assurance of success. Let us give the ex-intern a chance in his hospital or to use a common phrase, let the hospital give him "a square deal."

42 GATES AVENUE.

METRORRHAGIA.

BY EMIL SCHWARZ, M.D.,

NEW YORK.

FROM THE PATHOLOGICAL LABORATORY, WOMAN'S HOSPITAL.

SINCE time immemorial hemorrhages from the uterus have been an interesting and difficult question for physicians who have had to deal with this most common symptom among the ailments of women. The question becomes more complicated because of the normal cyclic uterine hemorrhage occurring every twenty-eight days. The periodicity was attributed in the ages of superstition to the changes of the moon. It is only since the time of Virchow that anatomical considerations have put the physiology and pathology on a sound basis. Morphological changes are the only criteria on which to base conclusions concerning uterine hemorrhage just as truly as they are for all natural science.

In recent years histological studies have revised all the theories about the cause of uterine hemorrhage substituting biological phenomena for morphological data. This tendency seems at present to be overdone.

I shall try to give a short survey of the present aspect of metrorrhagia. Following the usual outline of pathological study, I start with *Intoxications* as causes for metrorrhagia. Phosphorus and arsenic are well known as causes of uterine hemorrhage. The different diseases of the blood and blood-making organs, different types of anemia, leukemia, purpura hæmorrhagica are usually accompanied by uterine hemorrhage.

Infectious granulomata (tuberculosis and syphilis) do not appear to have uterine hemorrhage as a symptom. Both of these diseases are very rare in the uterus, and the cascation and granulomata produced by these seem to cause rather a characteristic discharge than metrorrhagia. It is furthermore a very common belief that displacements of the uterus cause hemorrhage. This opinion needs restriction as is shown by the fact that even the correction of the displacement usually does not check the metrorrhagia. To this theme I shall refer again.

A very important factor among the different causes of metrorrhagia is tumors. Polypi myomata, sarcomata, and carcinomata, with their tendency to hemorrhage into the tumor itself are regular causes of bleeding. Real adenomata of the uterus have not been observed, or rather the term adenoma, meaning a benign tumor, is not applicable to the uterus. This brings us to the much discussed theme of endometritis as a cause of metrorrhagia. Up to 1907-8 Ruge's conception of the two kinds of endometritis, endometritis glandularis and interstitialis, has been the ruling one. This will be easily understood if one considers the way in which endometritis was diagnosed. Cases of metrorrhagia were, of course, always curetted, and in reality it was almost impossible not to find what might be described as one of these conditions in the curettings. On the other hand, Scanzoni, whose work appeared in the year 1863, introduced a new pathological picture in what he termed metritis chronica. According to him, sclerotic changes of the arteries and comparatively large arterioles, and the increased connective tissue in the myometrium were sufficient for the diagnosis of a chronic metritis, and the principal symptom of this disease was uterine hemorrhage.

Both Ruge's and Scanzoni's ideas were overthrown by the investigations of Hitschmann and Adler concerning endometritis, by Pankow, Teilharber, Ahreiner, and others, concerning metritis chronica. The work of Hitschmann and Adler especially was very fruitful as regards our present conceptions in the changes of the endometrium and the causes of hemorrhage. They showed that there is no endometritis glandularis. The different microscopic pictures were only expressions of the different menstrual phases of the endometrium. They divided the menstrual cycle into three phases: interval, premenstrual cycle, and postmenstrual, basing these phases upon histological differences. Their views are accepted today, and they have also given substantial proof that irregular uterine bleeding is associate with definite morphological pictures in the endometrium. Only a few details of this will be given here. They distinguish two kinds of irregular bleeding or menorrhagia: (1) menstruation starting regularly but lasting longer than normally, (2) menstruation setting in at irregular intervals.

Curettings which are usually made at the end of or during the progress of the uterine hemorrhage would show in a normal case the characteristics of the postmenstrual mucosa—namely, collapsed glands with scanty epithelium, the glands narrow rather than straight, showing one layer of cells. In the case of protracted bleeding these postmenstrual glands are corkscrew shaped, with two rows of cells. Corkscrew glands are characteristic of the premenstruum. If we find them in curettings obtained during the progress of bleeding and with several rows of epithelium and without the characteristic change of the single epithelial cell prevailing during the premenstruum, we can say that this morphological picture corresponds to a regular but protracted menstruation.

In the second case, where the menstruation sets in after entirely irregular intervals, we get the mixture of several phases in the same mucosa, although the histological appearance would not allow us to make the diagnosis without considering the case.

Scanzoni's hypothesis has been successfully attacked by Pankow and others since they have shown that uteri showing this characteristic change—namely, enlargement, fibrosis, angiosclerosis—show clinically very often no hemorrhage, while smaller uteri without any change of the myometrium may bleed intensely. Almost all the investigators of late have agreed that the cause lies in the ovary which naturally, being the cause of the monthly bleeding, might when diseased or abnormally functionating cause abnormal uterine bleeding.

Teilhaber thought that the sclerotic changes of the uterus were not the cause of hemorrhage, but he stated that a large amount of connective tissue prevents the uterus from contracting properly so that hemorrhage is not stopped. He called this uterine insufficiency and formed a new pathological

term, the apoplexy of the uterus. One very often finds in senile uteri hemorrhagic foci, which, however, as Simonds and Slavianski showed, were agonal hemorrhage in the uterine substance. From all the aforementioned investigations the final conclusions seem to be that hemorrhage is not caused by endometritis. The only form of endometritis recognized by the microscopist as well as the clinician is the endometritis with round-cell infiltration in the endometrium and the presence of large plasma cells, a condition which is comparatively infrequent. This leaves us the main symptom of endometritis, the purulent discharge, not the mucoid one.

Retrodisplacements of the uterus do not seem to cause hemorrhage in themselves through hyperemia of the uterus, but rather through adnexal disease usually connected with it or causing the displacement. The so-called endometritis climacterica in the beginning of the menopause does not seem to be due to the change in the uterus, the senile change in the ovary is the one factor causing the change in the uterus. It is also asserted that the irregular bleeding is due to the ovarian factor. At the onset of the ovarian function—that is, puberty—uterine hemorrhage is also very frequent, suggesting an ovarian cause. In conformity with the change of opinion regarding the morphology, the therapeutic measures had to be changed. Without referring to operative details, I will speak of remedies causing contractions of the smooth musculature.

If the ovary is the underlying cause of the hemorrhage, and without characteristic changes in the endometrium, it would seem irrational to give ergot preparations, hydrastin, etc., having in mind, according to certain authors, that only the pregnant uterus responds actively to these drugs, although it is doubtless true that ergotoxin in ergot causes contraction of the smooth musculature all over the body when given in sufficiently large doses. The uterus is a tube containing by far the largest amount of smooth-muscle contractile fibers, and there is no reason why ergot preparations should pick out just the fibers of the pregnant uterus to cause contractions. The pregnant uterus is, of course, far larger than the non-pregnant. But this does not mean that the smaller non-pregnant uterus, though comparatively poor in contractile substance, will not react. In reality a non-pregnant uterus when brought in contact with ergot in Ringer's solution contracts very promptly. Since arteries contract under the influence of ergot, why should not the uterus contract? It is a similar muscular tube with walls containing many times more muscle fiber than arteries.

That ergot is a very symptomatic remedy is true, but that it does not act at all on the non-pregnant uterus because the ovary causes the hemorrhage is an untenable proposition. Animal experiments on the uterus in situ are needed to demonstrate the action of ergot. Those advocating its use, as a result of clinical experience, have a rational basis for their claims, since even temporary cessation of hemorrhage is of value, and the ovarian trouble causing the hemorrhage is also, at least, intermittent.

A new element comes into the question of uterine hemorrhage with the demonstration of the noncoagulability of the menstrual blood. It has long been known that the menstrual blood did not coagulate after many hours, though blood from the systemic circulation of the same individual clotted at room temperature in eight to ten minutes. This fact has been used as an explanation for the long-continued uterine hemorrhages where no tumor or other explanation was demonstrable. This incoagulability, however, can be at best but one of the factors in metrorrhagia.

It will be necessary to state briefly the normal physiology of clotting in order to discuss the noncoagulability of menstrual blood. It was until recently held that the admixture of uterine secretions and other genital discharges prevent the menstrual blood from clotting. G. Hoppe-Seyler found in a series of experiments that the average amount of blood contained in the menstrual discharge is only 57 per cent.; the rest is mucus, serous secretions, etc. This admixture of mucoid liquid contains a considerable amount of salts, sodium phosphates, sodium carbonates, sodium chloride, etc. The coagulation of blood is retarded or inhibited by mixing it with weak alkaline or acid solutions. This theory was antagonized by the findings of Dienst, who in a few cases was able to produce a substance from endometrium-extract which inhibited the coaguiation of blood. This substance is an antithrombin, and this necessitates now a description of the modern views of coagulation.

Alexander Smith's theory that fibrin is produced by the uniting of the fibrinogen present in the blood plasma and the fibrin ferment furnished by the corpuscular elements of the blood was modified by the brilliant investigations of Morawitz, Fuld, Bordet and Gengou, etc. They found that the fibrin ferment is composed of a proferment called thrombogen, which is also present in the plasma, and the thrombokinase furnished by the blood platelets and leucocytes, but these two bodies form fibrin ferment, or, as it is called at present, thrombin, only in the presence of lime salts. The thrombokinase activates the thrombogen to form thrombin only when in contact with foreign bodies. So four conditions are necessary, thrombogen, thrombokinase, lime salts, and the stimulus of foreign bodies. If any of these elements are missing coagulation does not occur. For instance fibrogen normally present in the blood plasma is destroyed in phosphorus intoxication and in the cadaver. The lime salts are missing when they become precipitated by oxalates or sodium citrate. The thrombokinase does not act when the blood containing the thrombokinase is allowed to run into a tube, the inner walls of which are covered with paraffin, and even if the fibrin ferment is formed anti-ferments might inhibit its action, as, for instance, in the case of hirudin, the extract from leaches, when it is mixed with the blood. The thrombokinase might also be excluded from action by an antikinase which is present in cobra and rattlesnake poison. Antikinase can also be produced by the injection of kinase into the blood. Doyen succeeded in producing an antithrombokinase solution from rabbit liver, and Dienst, as I mentioned before, from the endometrium. They, however, did not succeed in producing antithrombin in a pure state. Fibrin ferment or thrombin can be obtained only in mixtures with other liquids. This, of course, leaves the question open whether the extract is really a specific antithrombin or only a substance inhibiting coagulation in the same way that a diluted acetic acid would act. Although the few experiments of Dienst are readily accepted by physiologists, the theory concerning the admixture of the alkaline secretions of the uterus is still very strongly defended.

It is not justifiable to say that a ferment produced in the endometrium prevents coagulation, because it has not been sufficiently proven that the substance obtained by Dienst becomes inactivated if kept for an hour at 58° C.

The question of metrorrhagia is not much cleared by the observation of the incoagulability of menstrual blood because it is a matter of common observation that menorrhagia is often accompanied by the discharge of clotted blood. This is true of menorrhagia, metrorrhagia, bleeding from myomata uteri, etc. This, of course, might be explained by either theory, (1) assuming that there was not a sufficient amount of alkaline fluid mixed with the blood, and (2) assuming that the flow of blood was so intense that there was not sufficient antithrombin to counteract the fibrin ferment contained in the blood. From this short excursion into the theory of the incoagulability of menstrual blood one might easily conclude that it requires exact and irreproachable investigations to solve the question.

Conjectures without exact experimental work and statements, as, for instance, that the endometrium is an organ with an internal secretion, will never help the cause.

I have given in the foregoing the present views, the causes, and the pathological anatomical findings in metrorrhagia. From the many hundreds of curettings examined by Dr. L. W. Strong and myself, I wish to state that we could not help but approve of Hitschmann and Adler's views on the question of endometritis and its relationship to metrorrhagia.

I have also examined six uteri from cases in which the histories and exact pathological findings were accessible to me and found that Pankow's assertions are to a certain extent correct. These six uteri were removed from women suffering from metrorrhagia and showed macroscopically and microscopically no disease of the adnexa nor any tumor, myoma, or the like in the uterus. Only one case showed a real fibrosis of the myometrium and hyaline degeneration of the blood vessels; the remaining five uteri did not show any sclerosis of the myometrium nor any changes in the blood vessels which would enable us to ascribe the clinical symptoms to pathological changes. In these cases undoubtedly the morphologically normal adnexa have been responsible for the metrorrhagia by a dysfunction. This seems to be especially prevalent at the beginning and the ending of the functional life of the ovaries.

The endometrium shows in comparison with other mucous membranes singular features; the capillaries which rupture every twenty-eight days in numerous points, and the stroma which shows at that time intense changes furnish numerous possibilities of aiding hemorrhagia.

Local factors in the uterus at present still unknown may also be the cause of metrorrhagia. Neither the theory of an antithrombin causing the lack of coagulability nor that of a hormone produced by the ovaries explains satisfactorily the causes of this very frequent ailment of women.

Therefore, the decided prejudice which exists against the older therapeutic measures on the ground of modern theories is not fully justifiable. Until the rather vague biological and morphological phenomena encountered in experimental and clinical investigations are based on satisfactory proofs the gynecologist has largely to resort to his individual experience in the use of remedies checking the uterine hemorrhage.

THE DIAGNOSIS OF CHRONIC BRONCHITIS.

By JOHN M. CRUICE, A.B., M.D.,

PHILADELPHIA, PA.

PHYSICIAN TO THE HENRY PHIPPS INSTITUTE OF THE UNIVERSITY OF PENNSYLVANIA, AND TO THE OUT-PATIENT DEPARTMENT OF ST. AGNES' HOSPITAL; INSTRUCTOR IN MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA; FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, AND MEMBER OF THE JOHN MORGAN SOCIETY.

In looking over the reports of the medical dispensary in several hospitals I was impressed with the number of cases that had been diagnosticated chronic bronchitis. One dispensary with 2,193 cases in the year had had 44 cases of chronic bronchitis compared to 83 cases of pulmonary tuberculosis, another with 1,038 cases had had 51 cases of chronic bronchitis compared to 22 cases of pulmonary tuberculosis and still another with 2,963 cases had had 160 cases of chronic bronchitis compared to 117 cases of pulmonary tuberculosis. These figures are taken from three prominent hospitals and it is not unfair to suppose that rather similar figures could be found in the reports of other hospitals. How often is it justifiable to make a diagnosis of chronic bronchitis? Is it not almost always a symptom of some underlying condition?

Chronic bronchitis is said to follow repeated attacks of acute bronchitis or even one attack of acute bronchitis if the infection is severe enough. In the cases of chronic cough there is very frequently some underlying pathological condition in the chest or some systemic condition and this is the diagnosis which should be made, the chronic bronchitis being simply a symptom of that lesion.

It is not an unusual history in tuberculosis dispensaries to have cases come there for diagnosis who have been treated for a varying number of months as chronic bronchitis. Examination frequently shows those cases to be more or less advanced cases of tuberculosis. I have examined this winter a child who for a year or more had been treated for chronic bronchitis. She gave a history of repeated attacks of acute bronchitis which was finally thought to have become chronic. Examination showed all the signs of advanced tuberculosis with cavity formation and all the distressing septic symptoms so often seen. A few weeks ago I saw a young Italian who said that in December, 1912, he had been treated for a severe cold. Since that time he had had a cough and his physician told him he had a chronic bronchitis for which he had been treating him. A careful inquiry revealed a rather typical case history of pneumonia in December, 1912. Examination of his chest showed an infiltration at the right apex and a fibroid condition in his right lower lobe, the probable site of his acute cold in December, 1912.

There are numerous conditions which, interfering in one way or another with the circulation of the blood in the lung, are accompanied by chronic bronchitis. The underlying condition being missed the case is diagnosticated chronic bronchitis. Some of these are cardiac conditions, especially mitral disease, emphysema and enlarged bronchial glands. At times there may be a combination of a couple of these causes as in the case of an old woman I saw who had been treated for some time for chronic bronchitis. Examination disclosed quite a marked degree of emphysema and a mitral regurgitation with some loss of compensation. Under treatment directed particularly to her heart the bronchitis cleared up to a great extent.

The enlarged bronchial glands causing chronic cough are usually met with in children. Holt says "the cough often occurs in severe paroxysms, the character of which is very much like pertussis. The attacks are apt to come on about the middle of the night for months. On account of the loss of sleep the patient's general health may be considerably undermined." The diagnosis of enlarged bronchial glands is not an easy one to make. But the condition should be held in mind in all cases of children with chronic cough the cause of which is not apparent.

Bronchiectasis is a condition that is quite frequently missed and the case is diagnosticated chronic bronchitis. In these cases a careful history of the case is often a great help, as the condition frequently follows a pneumonia or a pleurisy. There is the copious more or less fetid, thin, mucopurulent expectoration. The cough is more or less paroxysmal and occurs generally in the mornings. Careful examination of the chest will generally show physical signs not in keeping with a simple chronic bronchitis. The majority of the cases of chronic bronchitis occurring in the old are cases of chronic bronchitis developing on a senile emphysema and should be diagnosticated as such.

It is so important for the welfare of the patient suffering with a chronic cough to make a correct diagnosis that we should leave no stone unturned to arrive at our end. The diagnosis of chronic bronchitis often covers a multitude of sins and occupies a position to chronic cough that the diagnosis of malaria or influenza does to some obscure fever. The majority of mistakes in the diagnosis are not due to ignorance or lack of skill but more often to carelessness on the part of the examiner. Lavenson in a recent article on the failure to diagnosticate tuberculosis in its early stages found in the analysis of the method of examination of 54 cases that: "In 13.8 per cent. of the cases neither physical examination nor sputum examination was made, nor was the temperature taken. In 52.7 per cent. of the cases a physical examination alone was made. In 12.8 per cent. the temperature was taken and a physical examination was made, but the sputum was not examined. (In one of the cases included in this group the patient had no sputum at the time the other examinations were made.) In 8.3 per cent. the temperature alone was taken. In 4.1 per cent. a physical examination was made and the sputum was examined but the temperature was not taken. In 5.5 per cent. of the cases the patient, referring the complaint to the larynx, sought a laryngologist and in those cases only a laryngeal examination was made." It seems remarkable that these facts should be so. It is hard to believe that in a suspected case of tuberculosis an examiner would fail to make a physical examination, or to take the temperature, or to examine the sputum. It is, however, in this way that the majority of wrong diagnoses are made in tuberculosis and other medical conditions.

The cause of a chronic cough often requires careful and painstaking examination for its discovery, therefore we should make use of every diagnostic means at hand and remember that chronic bronchitis *per se* is rare. The most usual conditions that are mistaken for it are pulmonary tuberculosis, emphysema, fibrosis of the lung following pneumonia or pleurisy, and some form of heart disease.

1815 Spruce Street.

A PRELIMINARY REPORT ON A METHOD OF TREATMENT FOR DIPHTHERIA CARRIERS.

By H. R. MILLER, M.D.,

NEW YORK.

HOUSE SURGEON, MOUNT SINAI HOSPITAL.

Although I have been able to observe only a small number of cases, I have been prompted to report this method for the treatment of diphtheria carriers because of its apparently great value. The method consists in thoroughly spraying the throat with a solution varying in strength from ¼ to 1 per cent. of the usual 40 per cent. formaldehyde solution. The patient's throat is sprayed one hour before, or two hours at least after the ingestion of food or fluid. The spray is usually used every three or four hours except during sleep. The throats were sprayed daily and cultures taken from five to eight hours after the solution had been used. When the throat became free from bacilli, later confirmatory cultures were made. Because formaldehyde acts better upon organic material when used warm or almost hot, the solution used in our last five cases was warmed in a corked bottle before use. It was freshly prepared daily. In general I would advise that one begin with a solution of $\frac{1}{4}$ or $\frac{1}{2}$ per cent. made up from 40 per cent. formaldehyde. When necessary, the solution can be increased to 1 per cent. and be less frequently applied. Three, four, five or even six days of treatment may be required, but there should be persistence in the treatment. The urine should be examined daily so as to discover any effects on the kidneys. In none of the cases which I have treated has there been any evidence of any renal irritation. In the series of cases observed thus far no case failed to become diphtheria-free except one which was not treated under the author's supervision.

Case I.—C. M., 11 years of age. In February, 1913, the patient had an attack of what clinically appeared to be follicular tonsillitis, but a pure growth of diphtheria bacilli was obtained. Antitoxin was used with good effect on the symptoms, but the bacilli persisted. Four weeks later a similar attack developed. Antitoxin was again used. The bacilli persisted in spite of the use of iodine, potassium permanganate, bichloride of mercury, argyrol, and sprays of the cultures of the *Staphylococcus aureus*. A $\frac{1}{4}$ per cent. solution of 40 per cent. formaldehyde was used in the form of a spray three times a day for two days, and twenty-four hours later and five days later diphtheria bacilli were no longer found.

Case II.—Observed by Dr. M. H. Bass. Child eight years of age, with mild tonsillar diphtheria. Culture remained positive for three and one-half weeks in spite of the use of tincture of iodine, spray of peroxide of hydrogen, cultures of *Staphylococcus aureus* three times a day for three days, and bichloride of mercury 1-10,000, three times a day for three days. A ¼ per cent. solution of 40 per cent. formaldehdye was then used three times a day for two days, and cultures made twenty-four and forty-eight hours later showed no diphtheria bacilli.

Case III.—Observed by Dr. E. Libman. The patient was a woman sixty-eight years of age who had patches of membrane on both tonsils and on the right side of the uvula. Antitoxin was used and the membrane disappeared within two days. Four days later bacilli were still present in the throat. A $\frac{1}{4}$ per cent. solution of 40 per cent. formaldehdye was then used, and one day later and five days later cultures no longer showed diphtheria bacilli.

Case IV.—Observed by Dr. N. E. Brill and Dr. E. A. Aronson. Miss A., diphtheria of left tonsil and pharynx. Antitoxin was not used because of the presence of cardiac disturbance. Two throat cultures on successive days showed diphtheria bacilli. On the

evening of the third day the throat was sprayed every three hours with ½ per cent. of 40 per cent. formaldehyde solution. On the fourth day the spray was reduced to ¼ per cent., because of the mild irritation of the throat. The spray was continued on the fifth, sixth, and seventh days, but at intervals of five hours, and cultures on each of these days showed no diphtheria bacilli.

The following four cases were observed on the Surgical Service of Dr. A. A. Berg.

Case V.—J. P., three years of age. Tracheotomy done December 4, 1913, as a preliminary step to removal of laryngeal polyp on January 6, 1914. January 30, another portion of the polyp was removed. From the tracheal opening there was considerable thick mucopurulent secretion containing diphtheria bacilli. Cultures were found positive on March 5 and 6. The formaldehyde spray was used every three hours on March 7 and 8. Cultures taken on March 8 and 9 again showed diphtheria bacilli. On the latter day the spray was used every four hours, and the next culture was reported negative. Cultures were also negative on March 10 and March 15. In this case the trachea was cleared of diphtheria bacilli within forty-eight hours. The child was so intractable that throat cultures could not be taken. For the same reason the spraying within the first twenty-four hours was almost valueless.

Case VI.—M. L., 12 years of age, admitted to the hospital for the cure of tracheal fistula. March 6.—Routine culture showed diphtheria bacilli. Throat was sprayed with a ¼ per cent. solution every hour from eight to eleven, and at midnight a throat culture was found negative. March 7.—Throat sprayed every three hours. March 8.—Culture from tracheal wound reported negative. Spray continued until March 11, and cultures taken on that day and every subsequent day until March 15 proved negative.

Case VII.—R. O. 22½ months of age, admitted to the hospital for empyema. March 7.—Routine culture showed diphtheria bacilli. March 8-9.—One-half per cent. spray used every four hours. Throat cultures on both days negative, as also on March 9, 10, and 15.

Case VII.—R. O., 22½ months of age, admitted to the tuberculosis of cervical lymph nodes. March 7.—Routine culture reveals diphtheria bacilli. March 8, 9, 10.—A ½ per cent. solution was used every four hours, but the cultures still showed diphtheria bacilli. March 11.—Spray continued, increased in strength to 1 per cent. and used four times a day. Eight hours after the last application the throat culture showed no diphtheria bacilli. Cultures were also negative on March 13 and 15.

The procedure which I have suggested is a simple one and does not produce any untoward symptoms. It will be of interest to determine whether the spray suggested in this communication will influence the clinical course of diphtheria, and also whether the accessory sinuses can be cleared of diphtheria bacilli by its use. Because of the good results obtained in the series of cases here reported, I would suggest the use of the spray in acute cases of diphtheria in which antitoxin has already been administered, also its prompt use in cases where antitoxin is for some reason or other withheld temporarily or permanently.

I wish to thank the gentlemen whose cases I had the privilege of studying, and Dr. Libman for kind assistance.

Postabortal Icterus.—Andérodias and Drouin report two cases of this condition. In the first of these the jaundice was the result of a septicemia. In the second case the icterus occurred twenty-four hours after an intrauterine injection of non-sterile water. The urine of this patient contained a large quantity of hemoglobin, which may have been of hematogenous or of urinary origin. In the former event it may have been the result of a toxic hemolysis. In the latter event the blood that may have escaped from some part of the urinary tract would account for the hemoglobinuria.—*Journal de Médecine de Paris.*

PEDAL TIC.

By GUSTAV F. BOEHME, JR., B.S., M.D.,

NEW YORK.

NEUROLOGIST TO THE WEST SIDE GERMAN DISPENSARY AND HOSPITAL; ASSISTANT PHYSICIAN, NEUROLOGICAL INSTITUTE; CLINICAL ASSISTANT, DEPARTMENT OF NEUROLOGY, VANDERBILT CLINIC.

In the last few months capable phychanalysts have presented cases of torticollis (Pierce Clark) and various other spasmodic conditions which have succumbed to their methods. It is my purpose here to present an interesting case of pedal spasm which was cured in an extremely brief time by methods closely simulating theirs.

J. S., a native of the United States, 29 years old, and a clerk by occupation, consulted me on April 11, 1914, for the following conditions: Four years ago he noticed a twitching of his right foot while seated at rest; at times the left foot would be involved in similar movements. He felt extremely fatigued and did not feel desirous of walking any decided distances. The condition gradually grew worse till at the time of the history the spasms occur at night while in bed, when seated and on occasions when walking. His feet then seem to go from under his control, the right foot swinging inward, and he walks as if intoxicated. There is with this an occasional slight pain in the knees. Otherwise he feels well. There are no other subjective complaints. Lues is denied.

As to previous illnesses, he had measles in childhood; five years ago he was operated upon for the removal of a nasal spur, and two years ago he had some slight gastric disturbance. Family history is negative except for gastric cancer of father.

His physical examination was negative except for increased tendon reflexes; a diminution of corneal reflexes and a slight hyperesthesia and hyperalgia in the iliac and gluteal regions.

Feeling that my patient had no organic condition present, the determination of his so-called "subconscious" complexes was determined upon. On April 11 he stated that he had masturbated for a few years; that he had married at 27 years and was perfectly happy, having one child of 13 months of whom he was very fond.

On April 15 he again returned, and I then elicited the following further facts: Four years ago he had been in love with a young lady who had broken her troth to him. He brooded over this for a long time until he met his present wife, when he said his interest in the former inamorata ceased. (A substitution for a repression.)

His present home life proves to be far from a happy one. While his wife is a fair helpmate she tends to be very apathetic. He works hard all day, and upon returning home he is desirous of her company. She, however, falls asleep on some nearby couch, while he sits reading, whereupon his feet immediately commence to twitch and he feels much worse.

As far as his sexual relations go, he says at times things seem normal, on other occasions his sexual feelings are outraged by her general apathetic attitude, all of which has greatly obtunded his affection for her. Certain factors are to be noted, viz.: (1) His unfortunate condition at home, (2) his previous love affair, (3) his occupation, (4) the foot spasm.

The latter I explained as follows. Most of us when seated, crossing one limb over the other, as is generally done while reading, tend to oscillate the suspended foot. This, too, is generally the right one, the one most affected in our patient. If at all mentally perturbed the swinging is more pronounced, so much so, in fact, that the condition frequently becomes noticeable. My patient was a

clerk. In this occupation he sat upon a high chair with his feet dangling down, at times crossed. When worried he twitched his feet. When he finished the day's work he returned to his home, a thoroughly unsatisfactory environment, and here while reading his thoughts would wander, his worries would crowd into his consciousness, and the foot-twitching, at first voluntary, would begin. Gradually, subconsciously, the tic gained the ascendancy, and we have the condition presented in the picture before us—a pedal spasm of psychoneurotic origin.

Treatment consisted in explaining to him the mechanism of his condition, improving his general hygiene, and insisting upon rather prolonged walks in the evening with cheerful friends.

Three days after the condition was explained to him his movements were much improved. On May 2, 1914, all twitchings had ceased, and he declared that it was a relief mentally and physically after four years to understand his ailment and to feel that he had no fear of its recurrence.

He may, however, have a recurrence; this depends not so much upon his physical condition, but rather upon the clearness with which he interprets these symptoms. His cure may be attributed to the partial psychanalysis employed, and again demonstrates that its principles must never be forgotten whenever a tic or a spasm of any variety presents itself.

2131 Broadway.

Medicolegal Notes.

Malpractice—Care and Skill Required—Insufficient Evidence.—In an action against a physician and surgeon for malpractice it was alleged that the negligence complained of consisted of his not bringing and keeping the broken parts of the bone of plaintiff's leg into apposition, and while the broken parts overlapped in placing them in a wire splint and afterwards in a plaster cast, and permitting them to remain in that position for sixteen weeks. It was held that there was no error in refusing to make the complaint more definite and certain.

If the plaintiff, a regularly licensed physician, with reasonable diligence employed the skill of which he was possessed in treating the case, it was held that he was not liable for an error of judgment, and that the mere fact that an untoward result ensued was not in any sense evidence of negligence. There are so many elements combating the surgeon in his efforts to restore a patient to bodily soundness that he can do no more than exercise his best skill and judgment to accomplish the desired result. "The distinction between an error of judgment and negligence is not easily determined. It would seem, however, that if one, assuming a responsibility as an expert, possesses a knowledge of the facts and circumstances connected with the duty he is about to perform, and, bringing to bear all his professed experience and skill, weighs those facts and circumstances, and decides upon a course of action which he faithfully attempts to carry out, then want of success, if due to such course of action, would be due to error of judgment, and not to negligence. But if he omits to inform himself as to the facts and circumstances, or does not possess the knowledge, experience, or skill which he professes, then a failure, if caused thereby, would be negligence." It was admitted that the defendant diagnosed the case as a fracture of the right femur. The testimony showed that he endeavored to ascertain by palpation whether the parts of the bone were in apposition, and that he applied proper bandages to maintain that position. It was admitted that he installed extension weights to overcome the natural muscular contraction tending to displace the bone. The treatment was performed in a public hospital in the presence of another physician and the attendant nurses. There was no shortening of the leg shown or sidewise displacement of the foot during the defendant's connection with the case. It was not until after the plaintiff had begun to sit up and move around on crutches and had taken an automobile excursion that a misplacement or nonunion was suspected. The case was held to be one where the surgeon had treated a case in which the result was a failure. There was nothing to show that he did not do his best with what skill he possessed. To hold him liable without proof of some careless act or omission of his which produced the undesirable consequence would be to make him an absolute insurer of success in every operation which he undertook. Such a rule would be too drastic to be applied to the medical and surgical profession, and is not borne out by the authorities. There was a hiatus in the testimony on behalf of the plaintiff between the time the defendant ceased to treat him and the subsequent discovery of the nonunion of the bone which broke the connection of the defendant with the unfortunate result so far as negligence was concerned. Judgment for the plaintiff was reversed, and a judgment of nonsuit was directed to be entered.—Hill v. Shaw, Oregon Supreme Court, 137 Pac., 229.

Medical Associations—Trial of Member Notwithstanding Acquittal by Court.—The Hennequin County Medical Society is a voluntary association of physicians and surgeons. One of its by-laws provides as follows: "A member who is guilty of a criminal offense, or of gross misconduct either as a physician or as a citizen, or who violates any of the provisions of this constitution and by-laws shall be liable to censure, suspension, or compulsion." One of its members was acquitted in the district court of the county of the crime of manslaughter in the first degree. The indictment was based upon an alleged criminal operation. It was held that the society might try the member for the acts involved in the criminal prosecution notwithstanding his acquittal by the district court.—Miller v. Hennequin County Medical Society, Minnesota Supreme Court, 144 N. W., 1091.

Homicide—Causal Connection.—In a murder case it appeared that the defendant inflicted knife wounds on one Miller, one of the wounds being a deep stab which penetrated the left lung. Miller was a large, heavy man, in the prime of life. He was in good health except for alcoholism. Forty-eight hours after the assault he developed pneumonia, and died from the disease a week later. The pneumonia the lung which was pierced only. The surgeon who dressed Miller's wounds testified that in his opinion the pneumonia was caused by infection through the wounds, particularly the stab which pierced the left lung. Another physician, who attended Miller after the assault until his death, testified that he was unable to give an opinion whether the bacillus was taken into the lung by inhalation or was introduced by the knife of the defendant. The evidence, it was held, did not leave the cause of death a matter of speculation or conjecture, but was sufficient to justify the conclusion that the pneumonia germ was not inhaled, but entered the lung on the knife blade of the defendant, or through the puncture made by the blade, and therefore that the defendant caused the death, and was guilty of murder. —State v. James, Minnesota Supreme Court, 144 N. W., 216.

Operation Without Consent—Assault and Battery.—In an action for assault and battery against a physician and surgeon it appeared that the plaintiff had stepped upon a nail which penetrated the great toe of her right foot causing inflammation. The defendant advised an operation some 60 days after the injury, by making an incision in the toe so as to drain the joint. This was agreed upon and the operation was performed while the patient was under an anesthetic. In the course of the operation a sesamoid bone was removed, and the action was based upon this removal. It was not claimed that the operation was unskillfully performed, but that the defendant had agreed not to remove any bones from the foot. The plaintiff contended that the removal of the bone without her consent was wrongful and unlawful, and that her foot was permanently injured thereby. It was held: (a) That the defendant had no authority to remove the bone without the plaintiff's consent, either express or implied. (b) That she did not expressly consent, and whether or not her consent was implied from the circumstances was a question for the jury to determine under all the evidence. (c) That, if the plaintiff did not consent, the removal of the bone was wrongful and unlawful, and constituted in law a trespass upon her person and a technical assault and battery. Judgment for the plaintiff was affirmed.—Bolater v. Strain, Oklahoma Supreme Court, 137 Pac. 96.

New York, July 25, 1914.

THE ALBUMINOUS CONTENT OF SEROUS FLUIDS.

WITHIN recent years considerable attention has been paid to the cytology of transudates and exudates, but relatively little has been learned regarding the chemical differences of these fluids. The albuminous content of the latter has been made the subject of a special study by Mosny, Javal, and Dumont, who report their results in *La Presse Médicale*, June 24, 1914. The investigation of the amount of albumin contained in serous accumulations in more than fifty patients furnished data of eminent practical value in diagnosis. The method employed was to precipitate the albumin and then weigh it. The most striking differences were between the transudates and the exudates.

Serofibrinous pleurisy is characterized by the high content in albumin which varies between 40 and 66 grams per liter. There is no difference between primary or secondary tuberculous pleurisy and that of streptococcal origin as regards the albumin content. In purulent pleurisy the albumin attains a high figure, approaching that of the blood, and fluctuating about the figure 70 grams. There is no relation between the hemorrhagic character of a fluid and its albuminous coefficient. In a recurring infectious exudate the albumin figure remains stationary. In pleurisy of cancerous origin the amount of albumin in the fluid is comparable to that of the microbic exudates. Likewise, the hemorrhagic condition of the fluid is not accompanied by any change in the albuminous content.

The greatest contrast exists as regards the relative content in albumin between the transudates and the exudates. The figure for the former is from 3 to 26 grams per liter. The rule is laid down that any serous fluid containing less than 30 grams of albumin per liter must be regarded as a transudate. In the so-called cardiac pleurisies which have the typical clinical aspect of an inflammatory pleurisy the pleural accumulations have a polynucleosis approaching that of a purulent exudate, but resemble the transudates in their albuminous content. This is a distinction of considerable diagnostic value.

The transudates and the exudates of the peritoneal cavity follow the same laws as those of the pleura. The ascites of cirrhosis of the liver or of heart disease is hypoalbuminous (less than 35 grams per liter), while that of tuberculous peritonitis is hyperalbuminous (more than 40 grams per liter). In peritoneal cancer the albumin figure is likewise high.

The question now arises whether the isolation of special types of albumin in serous fluids furnishes any diagnostic criteria. It has been known for some time that there exists in certain of these fluids a small quantity of an albumin that is precipitated in the cold by very dilute acetic acid. This is a nucleoalbumin which has been closely studied by Patein and which is designated by his name. It is the presence of this substance upon which is based the reaction of Rivalta, namely, transudates do not yield any precipitate with slightly acidulated water while exudates give a marked reaction. Mosny, Javal, and Dumont find that whereas in the case of infectious exudates this reaction always occurs, it nevertheless fails in the case of so-called cardiac pleurisies.

Albuminodiagnosis cannot replace cytodiagnosis, although the two methods give identical results in the infectious pleurisies and in the cases of pure hydrothorax. But in the cancerous exudates and in the so-called cardiac pleurisies the former method has a value peculiarly its own. In the exudates of cancer there is no characteristic cytology, although occasionally an atypical cell may furnish a diagnostic clue. In some cases of cardiac pleurisy there may be a neutrophile polynucleosis, an eosinphilia, or even a lymphocytosis. These cellular changes which are the result of pleural irritation rather than of secondary infection are not accompanied by any change in the albumin content which remains low, and by reason of this fact enables one to make an exact diagnosis of the nature of the fluid. Sufficient data have been gathered, however, to show that the albuminodiagnosis of serous fluids is of real clinical value.

ENDOURETHRAL TREATMENT OF HYPERTROPHY OF THE PROSTATE.

HYPERTROPHY of the prostate, affecting, as it usually does, patients in the later years of life, perhaps enfeebled by other diseases and by septic absorption, presents a therapeutic problem often demanding the exercise of rare judgment as well as skill on the part of the surgeon. It seems almost incredible to us now that the true cause of the obstruction to the outflow of the urine remained unrecognized for so long.

Since the advent of the cystoscope and urethroscope, a number of methods for direct endourethral attack of the hypertrophied prostate have been devised. H. H. Young was one of the first to attack the prostate by this route, and devised the so-called punch operation for the removal of the prostatic bar—a method which has given very satisfactory results in his hands. Luys, however, criticises the method (*La Clinique*, June 12, 1914) on the ground that "one guillotines the vesical neck and acts only upon that; one is not able sufficiently to graduate its effects; besides, unfortunately, it

produces a hemorrhage which may be serious and which one cannot arrest immediately; and, finally, the operation cannot be applied in the presence of marked hypertrophy of the lateral lobes." Endoscopic examination of the urethra in cases of prostatism almost always shows two causes of mechanical dysuria: the forward bulging at the vesical neck, producing the prostatic bar; and the junction of the two hypertrophied lateral lobes, creating an anteroposterior tunnel extending from the prostatic bar to the posterior border of the verumontanum, in which runs the often markedly narrowed, elongated, and tortuous urethra. It is thus evident that in most cases not only should the bar be removed but the prostatic tunnel must be enlarged, so that the prostatic urethra shall no longer be compressed.

To accomplish this Luys recommends the galvanocautery and electrocoagulation (Oudin). After introducing the author's direct vision cystoscope, the area to be cauterized is anesthetized. He has found that there is very little pain from the cauterization and but little discomfort from the sensation of heat in the surrounding structures. The absence of pain is also partially accounted for by the passing of a strong current of air through the cystoscope, and this likewise serves to remove the smoke which is produced at the moment of cauterization so that the view is only momentarily obscured. Another advantage of the method is the almost complete absence of hemorrhage when cauterizing the posterior part of the prostatic lobes. As the verumontanum is approached the vascularization is much more marked. The incisions into the lobes are made with the galvanocautery and if there is enough bleeding to be troublesome this is controlled by electrocoagulation. The eschar from galvanocauterization is very insecure and may be evacuated immediately upon contact of the urine, thus allowing hemorrhage to continue; that from electrocoagulation, on the other hand, is very tenacious, and when the bleeding has once been arrested by this means there is very little tendency to immediate or secondary recurrence. One lobe is treated at the first sitting, another eight days later, and the treatment is continued at like intervals as long as is necessary for the destruction of the bar and hollowing out a large tunnel for the urethra. During the first few days after the cauterization there is very little if any improvement in urination, owing to the intense hyperemia following the burn; but by the fourth day the patient passes a much larger stream and there is constant improvement thereafter. At the end of about one month the mucous membrane of the urethra is found to be soft, pink in color, and without granulations. Luys admits that the endoscopic treatment of hypertrophy of the prostate requires considerable time and much patience on the part of the surgeon as well as of the patient; but in consideration of the excellence of the results, the slight amount of danger, and the fact that the patient does not have to enter the hospital but can attend to his regular occupation during the course of the treatment, he feels this method deserves acceptance and should be employed in suitable cases.

THE TECHNIQUE OF CECOPEXY.

ATTENTION was called recently in this column to the frequent coincidence of cecum mobile and movable kidney and it was said that when the latter condition called for operation it was often necessary to anchor the cecum and ascending colon as well. A number of methods have been suggested for this purpose. Wilms incised the parietal peritoneum and by blunt dissection made a pocket or "peritoneal pouch" into which the cecum was sutured. Rehn, Coffee, and others have simply stitched the cecum and ascending colon to the posterior parietal peritoneum. The most recent addition to the technique of cecopexy is contributed by Duval (*Revue de Chirurgie*, May, 1914). He quite correctly calls attention to the fact that it does not seem logical to attempt to fix an abnormally mobile organ to so extensible a structure as the peritoneum; and although success has followed this method in some cases, many failures have also been observed. He has accordingly adopted the technique of colopexy which he has described in conjunction with Quénu, namely, the fixation of the intestine to the tendon of the psoas parvus or, when that is lacking, to the inner border of the psoas magnus.

The technique is as follows: The patient is placed in the Trendelenburg position and an oblique iliac incision is made, extending as far as the external border of the rectus. The external oblique aponeurosis is split in the direction of its fibers, as also are the internal oblique and transversalis muscles, but as it is necessary to have ample access to the pelvis, the fibers of these muscles are also cut to the extent of about 1 cm. upward and downward at a point about corresponding to the center of the incision. A large retractor is now introduced, the cecum is delivered, and the small intestines pushed inward and upward, where they are retained by a large compress. The appendix is then removed, and the degree of mobility and dilatation of the cecum are ascertained, cecoplication being done, if necessary. The iliac artery is now located, and immediately outside of this the peritoneum is incised parallel to the artery and running from about the middle of the iliac fossa to the point of fixation of the colon to the lumbar fossa. This incision may be accompanied, or supplemented, by a gentle detachment of the colon to the extent of a few centimeters. This detachment has the advantage of creating a raw surface whose cicatrization will perhaps contribute to the fixation of the cecum. The lips of the peritoneal incision are dissected laterally, the tendon of the psoas parvus or, in its absence, the internal border of the psoas magnus is bared. In this latter contingency it is necessary to liberate the external aspect of the iliac artery and to retract the artery inward in order to pass the sutures. Three or four non-absorbable sutures (linen) are passed in the tendon of the psoas, then in the posterior aspect of the cecum including its posterior longitudinal band, so that the cecum is fastened securely in the iliac fossa. The lips of the incised iliac peritoneum are also sutured around the cecum. When a cecoplication has been done, the sutures

for the plication may sometimes be made to do service for the fixation to the psoas.

This seems the most rational technique that has yet been devised and well worthy of trial. Duval has employed the method in six cases with uniform success. It is recommended by the author as the method of choice for pure cecum mobile; but when, as Coffee suggests, this condition is coincident with loose right kidney, it should be equally valuable, in suitable cases, as an adjunct to nephropexy.

The Acetone Treatment of Inoperable Cancer.

The palliative treatment of inoperable cancer naturally calls for due exhibition of such remedies as have shown themselves of value individually in antagonizing some one or more symptoms, local or systemic, directed both to the tumors and their metastases and to the constitutional condition. In special institutions this may be carried out in great detail. Combinations and successions of individual measures may, through inhibiting proliferation and the pain, fetor and secretion, as well as by holding in check the cachectic ravages, lengthen the expectation of life in a certain number of inmates to a period hardly conceivable. We do not refer entirely to such resources as are actual rivals of the knife (radiotherapy, radium), but to minor measures as well. Among the latter is the acetone treatment, introduced by Gellhorn of St. Louis some four or more years ago. In the *Münchener medizinische Wochenschrift*, May 26, is a review by Vogt of Dresden of 100 personal cases of inoperable cancer treated by Gellhorn's method. After a thorough curettage, which forms a crateriform opening, pure, undiluted acetone is allowed to remain in the latter for 20 minutes; the cavity is then cleansed and tamponed, and the operation is repeated every few days. The immediate effect of the acetone is to produce a seemingly normal granulating surface.

Experimental Bright's Disease.

It has for years been a dictum that experiment on animals throws no light on human nephritis. Many irritating drugs, such as sublimate and cantharides have caused lesions in the tubular apparatus of the kidneys, but never in the other portions of the organ. The lesions thus induced have, moreover, been degenerative, and not inflammatory. In a recent report read before the K. K. Gesellschaft d. Aertze, Vienna (*Berliner klinische Wochenschrift*, June 15), Wiesel and Hess announce a solution of the problem, as follows: They injected uranium salts into the peritoneum and adrenalin in the blood, and thereby produced forms of acute and chronic nephritis differing in no wise from these diseases as they occur spontaneously in mankind. The disease begins as a degeneration of the convoluted tubes of the cortex, accompanied by genuine glomerulitis, which in turn is succeeded by hyaline degeneration and rapid appearance of interstitial foci with thickening of the blood vessels. The general process is degeneration of the parenchyma, with proliferation of the connective tissue. The succession is acute glomerulonephritis, subacute parenchymatous nephritis, and chronic contracted kidney. The rationale seems simple—adrenalin causes a marked constriction of the blood vessels in the glomeruli, so that the uranium retained therein exerts its peculiar toxicity.

News of the Week.

Plague in New Orleans.—The onset of illness in the first recognized case of plague in New Orleans was on June 24. Since then there have been reported five additional cases, the last one having taken ill July 18. According to Public Health Reports for July 17, measures for the eradication of plague at New Orleans have been mapped out and a force organized and put to work by Surg. Gen. Blue, acting under the direction of the Secretary of the Treasury. Dr. Blue has left Asst. Surg. Gen. W. C. Rucker in immediate charge of the work in New Orleans and has made a tour of inspection of Gulf and river ports. The measures being taken to eradicate plague and to prevent its spread from the city are as follows: All vessels leaving New Orleans are fended off from the dock 8 feet and rat guards 36 inches in diameter are applied to all lines and cables connecting the vessels with the dock. All gangways are guarded by watchmen while down. Prior to loading, all vessels are fumigated to destroy rats, sulphur being burned to make a 4 per cent. sulphur dioxide gas in the spaces fumigated. All general freight shipped overland and oversea is inspected to ascertain whether there is a possibility of its harboring rats or mice. Foci of plague, both human and rodent, are being treated by removal of the inhabitants; by fumigation of all buildings; and by deratization by the summary destruction of rat-harboring places, intensive trapping and poisoning, and enforced rat-proofing. Passed Assistant Surgeon Creel has been made executive officer in charge of the working force. Surgeon Corput is in charge of measures applied to outgoing vessels. Passed Assistant Surgeon Simpson is in charge of the field work in the city. Assistant Surgeon Williams is in charge of the laboratory. That portion of the city bounded by Canal Street, Claiborne Street, Louisiana Avenue, and the river has been divided into three districts, to be placed in charge of Assistant Surgeons Kearny, Carmelia, and Akin. July 10 the inspection of the bodies of all persons dying in the city was begun. This inspection is made daily between the hours of 6 and 9 P.M. The force making the rodent survey consists of 188 men engaged in trapping. They have in use 12,779 traps, which they are systematically setting throughout the suspected district and adjoining territory. Gangs of men have been started distributing rat poison. A laboratory has been fitted up and the laboratory examination of the rats trapped is in full force. On July 16, 1,039 rats were caught. The number of rats being caught is increasing at the rate of about 100 daily. The residents of the city are being informed of the nature of the situation and the necessity for their frank cooperation. This is being done through a publicity campaign and daily addresses at meetings. Effective rat-proofing laws have been drafted and submitted to the city authorities for enactment. Three plague-infected rats have been found thus far.

New Hospital to Open.—The opening of the new isolation hospital of Hartford, Conn., which was originally planned for July 1, has been postponed owing to delay in the finishing of the building. The hospital has cost about $100,000, and when it is completed Hartford will be well equipped to handle contagious cases.

Wide Drug Crusade.—Those who were instrumental in securing the passage of the Boylan anti-

drug law in New York State are said to be planning a national movement with a view to securing Federal legislation restricting the sale and use of habit-forming drugs. The chief difficulty so far encountered in securing good results in this State by the enforcement of the Boylan law has been the ease with which drugs can be obtained in New Jersey and Connecticut.

City Death Rate Still Low.—For the week ending July 11, the death rate was the next to the lowest in the city's history, being only slightly larger than that of the previous week when the low record was established. There were 1,180 deaths, or a death rate of 11.02 per 1,000 of population. The death rate for the first twenty-eight weeks of the year was 14.51 per 1,000, or 0.33 less than that for the corresponding period of last year.

State Vital Statistics.—During the month of May the total number of births in New York State was 19,675, with an excess of 657 males over females. The birth rate for the entire State was 23.5 per 1,000 of population, Batavia leading with a rate of 31.8, while New York City had a rate of 26. The lowest rates were recorded in the manufacturing towns where women are largely employed in mills and factories. The average birth rate in cities of the first class was 26.1; of the second class, 22.1; and of the third class, 22.9. The deaths throughout the State numbered 12,872, or 6,803 less than the total births. Oneida had the highest death rate, 30 per 1,000, while Watertown had the lowest, 9. The average for the entire State, exclusive of the deaths occurring in State institutions, was 15 per 1,000. For the first class cities the death rate was 15.31; for the second class, 15.1; for the third class, 16.6, and for the rural districts 15 per 1,000. Heart disease caused the greatest mortality during the month, 188 deaths per 1,000; tuberculosis was second, causing 160.4 deaths per 1,000; and Bright's disease third, with 128.5 per 1,000. The suicides numbered 133.

Record Immigration Year.—The highest record for immigration into the United States, made in 1907, has undoubtedly been broken in the fiscal year ending June 30, 1914. During the year which ended on June 30, 1907, foreigners to the number of 1,285,349 entered the country, and during the eleven months ending May 30, 1914, the number was 1,254,548, so that it is estimated that the total for this year will reach at least 1,355,000. There has been a marked increase in the number of persons, principally men, coming in from every country taking part in the Balkan war, although there was a greater number, 312,818, of Italians than of any other nationality.

Centenarian Dead.—William Clark, the oldest citizen of Cleveland, O., died at his home on July 14, aged 103 years.

Additional Milk Stations.—Six new milk stations were opened in New York City during the week of July 11, as a result of the work done by the Mayor's Special Committee on Baby Week, and still more will be opened shortly.

Medical Examinations.—Of the fourteen applicants who took the examination before the State Board of Health of Rhode Island recently, ten were successful and have received licenses to practise medicine in that State.

Roof Garden for Blind.—On the roof of the Bank of the United States at 81 Delancey Street, New York, there has been fitted up, through the generosity of the president of the bank, a roof garden for the blind of the neighborhood. Attendants will be present and a library of books in raised letters has been provided. Entertainments also will be given. The roof is one hundred feet above the sidewalk and is said to be the only place of its kind on the East Side.

Volunteers' Hospital.—The eighth annual report of the Volunteers' Hospital, New York, shows that during the year ending September 30, 1913, a total of 37,706 persons were helped. The major operations numbered 362; 1,214 ambulance calls were answered; and in the dispensary 11,879 new patients and 20,031 old ones were treated. The cost of maintenance for the year was $25,226, and at the close of the fiscal year the hospital faced a deficit of $2,517.

Reciprocity between New York and Virginia.—A reciprocity agreement between the State of New York and the State of Virginia has been entered upon for the endorsement of each other's medical licenses, providing the applicants have complied with all the specified requirements.

Personals.—Dr. GEORGE W. CRILE of Cleveland, O., has been selected by the Trustees of the American Medicine Gold Medal as the recipient of the medal for 1914, Dr. Crile being in the judgment of the trustees the American physician who has performed the most conspicuous and noteworthy service in the domain of medicine and surgery during the past year.

Dr. WILLIAM H. WALSH, superintendent of the Philadelphia Municipal Hospital for Contagious Diseases, and recently acting chief resident physician at the Philadelphia General Hospital, has been appointed medical administrator of the new Children's Hospital now in course of erection in Philadelphia. Dr. Walsh is a graduate of the Medico-Chirurgical College of Philadelphia.

Dr. ROBERT N. WILLSON, Jr., of Philadelphia, has been appointed visiting physician to the Philadelphia General Hospital in succession to Dr. William E. Hughes, resigned.

Dr. HERMAN B. SHEFFIELD of New York has been awarded the Alvarenga Prize for 1914, amounting to $180.00, for his essay entitled "Idiocy and the Allied Mental Deficiencies in Infancy and Early Childhood," submitted in competition under the motto "Corpus Mentis."

Dr. PAUL FRANKLIN CLARK, formerly associate in pathology and bacteriology at the Rockefeller Institute, New York, has been appointed assistant professor of bacteriology in the University of Wisconsin.

Dr. HOMER F. SWIFT, formerly resident physician in the Hospital of the Rockefeller Institute and assistant in medicine, has been appointed associate professor of medicine at the College of Physicians and Surgeons, Columbia University, and associate attending physician, Presbyterian Hospital, New York.

Rockefeller Institute Appointments.—The Board of Scientific Directors of the Rockefeller Institute for Medical Research, New York, announces the following appointments and promotions: Dr. Hideyo Noguchi, hitherto an associate member in the Department of Pathology and Bacteriology, has been made a member of the Institute. Dr. Alfred E. Cohn, hitherto an associate in medicine, has been made an associate member for the term of three years. Dr. Wade H. Brown, hitherto an associate in the Department of Pathology and Bacteriology, has been made an associate member for the term of

three years. The following assistants have been made associates in the departments specified: Dr. Harold Lindsay Amoss, Pathology and Bacteriology; Dr. Arthur William Mickle Ellis, Medicine; Dr. Thomas Stotesbury Githens and Dr. Israel Simon Kleiner, Physiology and Pharmacology; Dr. Alphonse Raymond Dochez, Medicine. Dr. Dochez has also been appointed resident physician in the Hospital of the Rockefeller Institute to succeed Dr. Swift. The following fellows have been made assistants: Dr. Frederick Lamont Gates, Physiology and Pharmacology, and Dr. Louise Pearce, Pathology and Bacteriology. The following new appointments have also been made: Mr. Chester Harmon Allen, M.S., fellow in chemistry; Dr. Alan M. Chesney, assistant resident physician and assistant in medicine; Dr. Harold Kniest Faber, fellow in pathology; Dr. Ross Alexander Jamieson, assistant resident physician and assistant in medicine; Dr. Benjamin Schönbrun Kline, Fellow in physiology and pharmacology; Dr. John Jamieson Morton, Jr., fellow in pathology; Mr. James Kuhn, Sr., M.A., fellow in chemistry; Dr. Joseph Richard Turner, fellow in pathology.

Gifts to Charities.—By the will of the late Elizabeth E. Smith of Philadelphia, the sum of $5,000 is bequeathed to St. Timothy's Hospital, Philadelphia. The Jewish Hospital of the same city receives a bequest of $500 by the will of the late Esther Baum. The Memorial Hospital, Johnstown, Pa., and the Washington and Jefferson Hospital, Washington, Pa., receive bequests of $1,000 each by the will of the late James M. Swank of Philadelphia.

Indian Conference.—A conference of the Physicians of the United States Indian Service of the Northwest was held at the Fort Lapwai Indian Sanatorium, Fort Lapwai, Idaho, on June 23 to 25, 1914. The conference was directly in charge of Dr. Joseph A. Murphy, U. S. Indian service. The sessions of the first day were devoted to a consideration of the question of tuberculosis among the Indians, the papers presented being supplemented by discussions and clinical demonstrations. Trachoma among the Indians was the topic for discussion on the second day, and on the third day the subjects of oral hygiene and general infectious diseases were taken up. After a general discussion of all the medical problems of the Indian Service, the conference adjourned to meet in Denver in 1915.

Coming Medical Meetings.—The twenty-seventh annual meeting of the Medical Society of the Missouri Valley will be held at Colfax, Ia., on Thursday and Friday, September 17 and 18, 1914. Various medical clinics will he held in Des Moines on Saturday, September 19. Further details as to program, etc., may be obtained by application to the secretary, Dr. Charles Wood Fassett, St. Joseph, Mo. The third annual convention of the American Association for the Study of Spondylotherapy will be held in Chicago on September 21 to 24, 1914, under the presidency of Dr. George C. Jarvis of Ashland, Ore. Programs may be obtained from the secretary of the organization, Dr. S. Edgar Bond, Richmond, Ind.

Obituary Notes.—Dr. Henry Clay Eno of New York, a graduate of Yale University in 1860 and of the College of Physicians and Surgeons, New York, in 1864, and for many years attending surgeon to the New York Eye and Ear Infirmary, died at his home on July 16, aged 73 years.

Dr. J. Clark Stewart of Minneapolis, Minn., a graduate of the College of Physicians and Surgeons, New York, in 1884, professor of the principles of surgery in the University of Minnesota College of Medicine and Surgery, and a member of the American Medical Association, the Western Surgical Association, and the Minnesota State and Hennepin County Medical Associations, died at his home, after a long illness, on June 25, aged 60 years.

Dr. Dean Samuel Ellis of Worcester, Mass., a graduate of the Jefferson Medical College, Philadelphia, in 1883, and a member of the American Medical Association, and the Massachusetts and Worcester District Medical Societies, died at his home, after a long illness, on June 30, aged 58 years.

Dr. George S. Morgan of New London, Conn., a graduate of the New York Homeopathic Medical College and Hospital in 1879, died at his home on July 5, aged 59 years.

Dr. Howard K. Edgerton of Lebanon, Tenn., a graduate of the University of Nashville, Medical Department, in 1889, and a member of the Tennessee State and Wilson County Medical Associations, died at his home on June 30, aged 48 years.

Dr. Ernest A. Hendricks of Tuscola, Tex., a graduate of the Birmingham Medical College, Birmingham, Ala., in 1908, and a member of the State Medical Association of Texas and the Taylor County Medical Society, died at his home from tuberculosis after a long illness, on July 1, aged 30 years.

Dr. John Joseph Mitchell of Boston, a graduate of the Harvard University Medical School in 1902, died recently at his home in Charlestown.

Dr. Sumner Ferdinand Quimby of Gloucester, Mass., a graduate of the New York University Medical College in 1881, for over thirty years medical examiner of Gloucester, and a member of the American Medical Association and the Massachusetts and Essex District Medical Societies, died suddenly at his home on July 10, aged 62 years.

Dr. Samuel Claggett of Petersville, Md., a graduate of the University of Maryland School of Medicine, Baltimore, in 1898, and a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, and the Frederick County Medical Society, died at the University of Maryland Hospital, from Bright's disease, after a short illness, on July 10, aged 41 years.

Dr. Rufus C. Webb of Rayne, La., a graduate of the Medical Department, Vanderbilt University, Nashville, Tenn., in 1883, president of the Rayne Health Board, and a former member of the Louisiana State Legislature, died at the Touro Infirmary, New Orleans, after a long illness, on July 5, aged 52 years.

Dr. James C. Rippard of Waycross, Ga., a graduate of the College of Physicians and Surgeons, Baltimore, in 1881, and a member of the Medical Association of Georgia and the Ware County Medical Society, of which he was a former president, died at his home from heart disease, after a short illness, on July 4, aged 57 years.

Dr. John H. Redding of Waycross, Ga., a graduate of the Southern Medical College, Atlanta, in 1881, and a member of the Medical Association of Georgia and the Ware County Medical Society, died at his home, after a brief illness, from pneumonia, on July 6, aged 65 years.

Dr. Harold T. Houg of Racine, Wis., a graduate of the Medical Department of Marquette University, Milwaukee in 1910, and formerly instructor in sur-

gery in that school, died at his home, after a long illness, on July 5, aged 28 years.

Dr. WILLIAM McD. AMOS, retired, of San Dimas, Cal., a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1871, died at his home, after a short illness, on July 2, aged 72 years.

Dr. ALBERT ROBERTS PYNE of Toronto, Canada, a graduate of the Toronto School of Medicine, in 1887, died at his home, from paralysis, after a long illness, on July 6, aged 65 years.

Dr. ANDREW BAYLIES of Worcester, Mass., a graduate of the New York University Medical College in 1879 and a member of the Massachusetts and Worcester District Medical Society, died at his home on July 7, aged 75 years.

Dr. EDMOND QUANDT of Detroit, Mich., a graduate of the Detroit College of Medicine in 1902 and county physician of Wayne County, died at his home, after a long illness, from tuberculosis, on July 5, aged 34 years.

Dr. GEORGE W. SEIFERT of San José, Cal., a graduate of the Jefferson Medical College, Philadelphia, in 1883, and a member of the Medical Society of the State of California and the Santa Clara County Medical Society, died suddenly at San Francisco, from heart disease, on July 2, aged 54 years.

Dr. AUGUSTUS B. KNOWLTON of Columbia, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1893, a member of the American Medical Association, the South Carolina Medical Association, and the Columbia Medical Society, and surgeon in charge of the Knowlton Hospital, Columbia, died at his home, after a long illness, on July 12, aged 46 years.

Dr. SHADRACH BURTON of Dallas, Tex., a graduate of the Eclectic Medical College of Pennsylvania, Philadelphia, in 1871, died at his home on July 6, aged 83 years.

Dr. AARON HERRING of Sparks, Kan., a graduate of the Ensworth Medical College, St. Joseph, Mo., in 1890, and a member of the Kansas and Doniphan County Medical Societies, died at his home, after a short illness, on July 9, aged 61 years.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RESEARCH DEFENSE SOCIETY, NEW PRESIDENT ON EXPERIMENTS—GENERAL VAILLARD'S LECTURE ON HOUSE FLIES AND THE PUBLIC HEALTH—MILK SUPPLY REGULATION—CONFERENCES.

LONDON, July 10, 1914.

AT the annual meeting of the Research Defense Society held last week the new president, Lord Lamington, delivered an address in which he took a somewhat unusual line, so far as public speeches go, though many of his remarks will be familiar to your readers. He held that the question of cruelty to animals should be considered in relation to that of the allegations of a brutalizing effect on the human mind. Many were perplexed by the preying of one class of animals on another as if their one desire was to wound. But really if the wishes of dogs or cocks could be consulted he presumed they would enjoy nothing more than a good fight. If it was not physical pain that caused most suffering to animals it was when the instinct of self-preservation took alarm that they suffered. Anyone who has observed wild animals when wounded knew that unless alarmed they seemed indifferent to the wounds. When people talked of killing old horses out of kindness he asked whether they might not prefer to live with all the disabilities of old age. One, he said, must recognize that pain does not affect animals with the same intensity as it does man, and further, uncivilized man does not feel it in the same degree as civilized and there are African races which seem totally insensible to it and refuse to take anesthetics for operations. He questioned whether those Indians who held the religious belief against taking animal life had not a sounder basis for their faith than anti-vivisectionists who had only the idea of stopping the infliction of pain. But they should remember that only 5 per cent. of experiments on animals were of a surgical nature or involved operation and many were made under anesthesia and the animals were killed before recovering consciousness. As to inoculations he had seen guinea pigs infected with cancer moving about and feeding without apparent discomfort. The Royal Commission's report would be considered to convince any one that the actual pain produced would be infinitesimal.

They should consider in comparison the mutilation of farm animals. In spring and early summer, said the president, the farms of the country seethe, so to say, with vivisection, sensitive organs being cut out of animals in full consciousness—this by the million annually. This is no exaggeration; one can find it in the statistics returned by the Board of Agriculture every year. Lord Lamington then diverted attention to benefits gained by experiments not only as regarded human life, but the life and health of the higher animals themselves.

The reports of the committee and treasurer were brought forward by Lord Knutsford, who expressed pleasure that the Dog's Bill had been rejected by the House of Commons for it would prevent research as to distemper—a horrible disease of dogs. He supposed any of the members would consent to an operation if it would save pain to thousands in the future and why should the dog be denied the same privilege? The report showed a satisfactory condition of the society which now numbers above 5,000 members and is very active, more than 100 meetings having been held during the year to promote its object, which is the steady education of public opinion concerning the true character of experimentation on animals and the advantages which have been gained therefrom in the past and are to be expected in the future.

After the meeting there was an exhibiton of moving pictures relating to the subject, *e.g.* bacilli of cholera and typhoid, spirochetes, trypanosomes, mosquitos, etc.

General Vaillard, the president of the Health Board of the French Army, has been here and delivered a lecture at the Royal Society of Medicine. He took for his subject "Houseflies and Public Health," opening with a description of the insects' life history and quoting Howard's estimate of the possible numbers that a single fly might produce in the climate of Washington, with which no doubt you are familiar. He then considered their influence on the spread of disease. In cholera a close relation had been noticed between the progress of the disease and the appearance or disappearance of flies. In the Spanish-American war and in the Boer war the army surgeons blamed the flies as carriers of typhoid. They found at Ladysmith that supplying filtered water to the troops did not eradicate the fever, but by simply protecting the food

from being visited by flies they rapidly reduced the epidemic. In the same way flies spread dysentery and infantile diarrhea. They also shared in the distribution of tuberculosis, granular ophthalmia, poliomyelitis, and leprosy. A fly might be charged with more infecting agents than the most polluted water—in some circumstances might be equivalent to pails of contaminated milk or water. A campaign against flies should be a part of all measures for preventing the dissemination of infectious diseases. To achieve success the public must be educated on the subject so that they would support the necessary measures. Individuals could easily prevent flies entering a room and to destroy them if they did enter means were not lacking. Traps, sticky and poison papers were numerous. Pyrethrum powder was very active when fresh and of good quality. Milk containing 15 per cent. of formalin gave excellent results. Cresol fumigations were not sufficiently known, but deserved special attention for they destroyed mosquitos as well as flies and were particularly applicable to kitchens, stables, yards, and generally all places where the insects could harbor for the winter. The suppression of these shelters was especially important as in them the insects produced new generations for the next summer. But the essential thing was to suppress their facilities for breeding. If they abounded in country places, army camps, dirty villages and towns, or parts of cities it was because they found putrescent or putrified matters which suited them for breeding in and for the development of their larvæ. Therefore the most effective measures were the destruction of these media and general cleanliness. The search for the shelters where they hibernate must always be a factor in every campaign against flies, for the destruction of the adults in their winter quarters entailed the suppression of the joint generation in summer.

General Vaillard mentioned some of the natural enemies of the fly—the spider, certain beetles, the centipede, etc.—but as they do not seem likely to help in the campaign I may pass them by. He credited the researches of English workers, the local government board, County Council, and some of our cities which, like Glasgow, had set a good example, with having begun the campaign and announced that in France the public were awaking and that at his instigation the "Conseil d'Hygiène et de Salubrité" of Paris had approved the propaganda, so it may be hoped that collective efforts may be made to abolish the scourge.

In the Standing Committee of the House of Commons there has been some more skirmishing about the Milk Bill. It was proposed to provide for the sale of a "certified" milk, the term being protected. This would follow your example in New York. The president of the Local Governing Board said he would willingly adopt the plan and Dr. Addison said that what was sold as "infants'" milk was often inferior to the ordinary supply, but of course "certified" would have to mean inspected. Objection was made that the plan would be received with dismay by farmers unless one word, certified or other, and one alone, were allowed and strictly protected. Another member supported the scheme as likely to benefit equally the producer and the consumer.

This milk question also bulked largely at the Conference on Infant Mortality on July 2 and 3 as well as at others, for we have been surfeited with conferences of late, those mentioned being followed on the 6th and 7th inst. by the Royal Sanitary Institute and on the 7th and 8th by that for the Prevention of Tuberculosis, to say nothing of those on the Insurance Act and on sanitorium treatment which have intervened.

OUR LETTER FROM VERA CRUZ.

(From Our Special Correspondent.)

BACILLARY DYSENTERY AMONG THE TROOPS—SUCCESSFUL TREATMENT WITH SALINES.

VERA CRUZ, June 30, 1914.

GASTROINTESTINAL disorders commenced in the United States soldiers immediately after disembarking from the transports in Vera Cruz and after eating food that had been unavoidably exposed to flies. There is dysentery present among the natives, and carriers are constantly present.

The city water is obtained from the Jamapa river and purified by slow sand filtration; following the arrival of the troops, these beds were overtaxed and a very poor quality of water resulted. All troops are using this same supply, but as the various regiments were infected in varying degrees, some heavily and others scarcely at all, other means of transmission than water were to be sought for.

Flies were numerous and kitchens unscreened, leaving an unavoidable exposure of food to these insects. Army officers from previous experience and careful scrutiny of conditions feel sure that so far a greater portion, at least, of intestinal disorders have been due to the mechanical transmission of infection by food and flies. Thus we again have Osler's familiar syndrome in preventive medicine—"flies, fingers, and food."

Enteritis (diarrhea) has been the greatest cause of admission, but these cases have responded promptly to a purge, rest, and liquid diet for a few days. This has not been the case with dysentery. From the first, patients have been admitted with a very severe type of bacillary dysentery. Incubation period varies from a few hours to two days, commencing with numerous bloody and mucous stools, abdominal pain, rectal tenesmus, and violent toxemia. The number of stools vary from fifteen to forty in twenty-four hours; they first show blood, mucus, bile-stained particles, and epithelium in single cells. Later, the stools become less numerous, blood and mucus greatly reduced, and epithelium appearing in masses or sloughs. The stools at this time are very offensive. About the tenth day of the disease, blood and mucus disappear, and the stools number about two a day; the tongue is clean, no pain, and the patient sleeps well. From now on convalescence usually commences and takes about a month.

There have been twenty-one dysentery admissions, three amebic—caused by the *Amœba hystolytica*—and eighteen bacillary. The medical officers here no longer recognize any other types of dysentery than amebic and bacillary.

Of these bacillary cases the more severe type appeared within the first six weeks after arriving, and although cases are being admitted from time to time, they are of a very much milder nature, are free from complications, and run an early and rapid convalescence.

Treatment of these bacillary patients has proven to be very interesting and instructive. It shows clearly that some methods recommended are not to be used, being not only worthless but dangerous. Of this class will be mentioned the opium and ipecac treatments. Both of these methods were tried and

the conclusion drawn is that both are harmful. The only death occurred in a case so treated. It is true that three cases recovered on which ipecac was used, with morphine to control the pain, but it was commenced late in the disease—about the eighth day. No improvement could be noticed following its administration. Ipecac was also tried on another case, that rapidly became worse after taking this drug; recovery took place when the patient was transferred to the United States. In the fourth case on which ipecac was used, the only death so far, the decline was very noticeable after taking thirty-five grains of ipecac salol coated.

This method of treatment having been proved an utter failure, anti-dysenteric serum and salines were tried. The serum was given in four cases, commencing on the eighth, third, fifth, and second day of the disease, respectively, reckoning from the first bloody stool. From ten to twenty c.c. per day was given subcutaneously about the chest. No improvement could be seen during five days of this treatment, and it was stopped. Of the four cases thus treated three developed complications; one, hemiplegia with acute local urticaria at the sites of inoculation; the second, multiple arthritis involving all large joints and a general erythema; the third case developed acute urticaria at all the sites of inoculation, becoming generalized in twenty-four hours, and covering almost the entire body. This patient suffered intensely, and, on the sixteenth day of the disease, developed multiple neuritis, involving both legs and the left forearm. These complications showed improvement within twenty-four hours, and with the exception of the hemiplegia almost entirely disappeared by the twentieth day.

Saline treatment is considered the treatment of election by the Army in Vera Cruz. Since it was commenced, there have been no deaths, and a steady improvement has been shown in all cases. Further, it has been used on patients believed to be as seriously affected as the patient that died under ipecac. It is carried out as follows: The patient is immediately put to bed and required to use the bed pan (rest is considered to be a very important element). The diet is liquid, and cornstarch enemata given low once a day, magnesium sulphate in 20 c.c. doses of the saturated solution is given every four hours, followed in one hour by ten drops of aromatic sulphuric acid in water. The stools are at first increased in number, but within two days they are greatly reduced in number and a marked improvement shown in quality, pain disappears, and the tongue becomes cleaner. When there is no longer blood, large sloughs, or offensive odor, and the number of stools is reduced to about three in twenty-four hours, the tongue at this time being clean, magnesium sulphate and aromatic sulphuric acid are reduced to twice daily. Bismuth subnitrate in 60 grain doses with 3 grains of salol is given every six hours. The following day, an egg and a piece of toast is added to the diet. The next day, magnesium sulphate is stopped as a routine, and the diet increased by adding a broiled scraped meat ball, boiled rice, boiled onion, eggs and toast.

Bismuth is decreased and the diet increased as the patient shows improvement. It is not uncommon to find a purgative necessary soon after commencing regular diet. Sodium phosphate in 15-grain doses is given before breakfast. The course of the disease and convalescence has averaged about a month in the more severe cases, and between two and three weeks in the milder types. Experience has shown that neither opium nor alcohol is to be given, pain is easily controlled by turpentine stupes to the abdomen, and alcohol is never necessary.

The amebic cases have responded promptly to emetine given hypodermically. In the single acute case the parasites disappeared in two days; emetine in one-third grain doses, three times a day, was used, but as a precautionary measure was continued for eight days after no parasites could be found in the stools. In the chronic cases it seems best to give emetine in one-third grain doses once or twice a day, but it is necessary to continue the administration much longer than in the acute form. Quinine enemata, although of questionable value, have been used as a routine. One quart of warm quinine sulphate solution (1-5,000) is given low twice a day.

1. Acute Abscess and Gangrene of the Lung. I. J. Walker.
2. The Anatomy and Physiology of the Seminal Vesicles with Regard to the Treatment of Their Lesions. W. C. Quinby.
3. Recent Studies in the Pathology of the Seminal Vesicles. J. D. Barney.
4. Arthritis Associated with Lesions of the Genitourinary Tract. E. G. Brackett.
5. The Erythema Group. H. Morrison.

1. Acute Abscess and Gangrene of the Lung.—I. J. Walker presents the following statistics based upon a review of the literature of the past ten years: Total number of cases of acute abscess of the lung, 132; males, 98; females, 32; sex not mentioned, 2. Total number of cases of acute gangrene, 40; males, 27; females, 5; sex not mentioned, 8. Average age in cases of acute abscess, 24.5 years; in cases of acute gangrene, 38.6 years. In acute abscess of the lung the right side of the chest was involved in 60 cases, the left in 45 cases; both sides in 5 cases; side not mentioned in 22 cases. In gangrene the right side of the chest was involved in 21 cases, the left side in 9 cases, both sides in 2 cases; sides not mentioned in 8 cases. In acute abscess the lobes were found to be involved as follows: Upper, 21 times; lower, 76 times; middle, twice; both upper and lower, 5 times. In twenty-eight cases the lobe was not mentioned. In acute gangrene: Upper, 10 times; lower, 24 times; middle, none; both upper and lower, 6 times. In acute abscess adhesions were present in 63, absent in 2, not mentioned in 57. In acute gangrene they were present in 17 cases; not mentioned in 23 cases. In 104 cases of acute abscess the lesions were single; they were multiple in 16 and were not mentioned in 12. The mortality in cases of acute abscess treated medically was 54 per cent.; in those treated surgically, 25 per cent. The mortality in cases of gangrene treated medically was 89 per cent.; in those treated surgically it was 44 per cent.

3. Pathology of the Seminal Vesicles.—J. D. Barney points out that vesiculitis may occur from infection with the tubercle bacillus. When one vesicle is involved its fellow may also be safely accused. Radiograms with collargol demonstrate the presence of inflammatory changes and their future as a diagnostic aid seems bright. Dense adhesions, usually surrounding the junction of the vas and vesicle, not only make operation difficult, but in most cases would make successful separation of the two structures impossible. Disease of the vas at its ampulla accompanies disease of the vesicle and the conservation of the former structure in the hope of preserving the continuity of the seminal duct is of doubtful value to the patient.

4. Arthritis Associated with Lesions of the Genitourinary Tract.—E. G. Brackett states that one may consider the joint manifestations connected with the genitourinary tract under two heads: (1) Those from the Neisser germ, and (2) those from the colon bacillus. The occurrence of an arthritis in the course of the acute urethritis is so familiar that only reference to it is made. The usual result is recovery with little or no impairment, but unfortunately this is not always the case. Of the less common and less favorable type there are two distinct forms. First, the acute monarticular or residaul monarticular involvement, running an acute and persistent clinical course, and resulting in loss of joint function. Its distinctive characteristics are the following: An arthritis of sudden appearance, giving evidence of a very acute synovial inflammatory involvement, as shown by acute pain, sensitiveness, deformity, which are persistent symptoms, and all of which indicate an inflammatory process in both parts of the capsule, a process which later shows an inherent tendency to marked contraction, with very strong adhesions or even destruction. In addition to these clinical signs, the presence of the bacillus is frequently found in very many cases. In other words, an acute inflammatory, non-suppurative destructive arthritis, a very distinctly different picture from that of the other forms of arthritis, and one which for contrast one may term a bacterial infection. The second type of infection is the more common variety. Its distinctive characteristics are an arthritis not of sudden appearance; perhaps with a history of previous attacks, often of acute but not extreme virulence; polyarticular in distribution, with marked but not extreme pathological changes in the capsule, with a strong tendency to the formation of adhesions, but not tending to destruction, except by prolonged and repeated attacks. In other words, one has a mildly inflammatory process, a multiple, slowly damaging arthritis from toxic infection. The injury in these cases is by interference with nutrition rather than by the acuteness of the inflammatory process. The second form of arthritis is the involvement of the joints by the invasion of the colon bacillus. Much less is known of the special joint manifestations of this than of the Neisser germ, and the actual differentiation must rest on the localization of the focus, and through this of the detection of the kind of infection. Although much less is understood of the characteristic joint manifestations of this infection, some general points are suggestive. The onset is sudden or gradual; the lesions are polyarticular, the spine is frequently invaded, and there is persistent acute involvement.

1. Treatment of Summer Diarrheas of Children.—F. M. Crandall states that four general measures of treatment are indicated—mechanical, dietetic, hygienic, and medicinal. At the outset mechanical measures are usually indicated to clear the digestive tract of fermenting material. Stomach washing is rarely necessary, but should be resorted to if the child continues to vomit curds or food or sour and putrefying matter. Prompt unloading of the lower bowell by means of irrigation is very important. High irrigations are valuable until convalescence is thoroughly established. At the outset of an acute diarrhea all food should be prohibited, but water should be given freely unless it induces vomiting. Milk should be resumed with great caution and sometimes must be long withheld. As a rule a laxative at the outset is strongly indicated. Castor oil is usually the one to be selected. A saline may fulfil the requirements very well. When the stomach is irritable calomel in small divided doses is frequently the laxative to be chosen. The type of disease should influence largely the laxative to be chosen. In the last half of June and the first half of July the prevailing type is the serous diarrhea, marked by large watery passages, ranging from a few up to twenty or thirty a day. During the following six weeks these serous cases are comparatively rare and true enterocolitis is more common. This means that the acute cases of the earlier summer have settled down to a true organic or inflammatory disease. During August the passages are of the thicker and more grumous type. New cases are much less frequent than in the earlier summer. In the late summer and early fall colitis appears, and the passages are of the so-called dysenteric type. They consist largely of mucus and blood and are accompanied by tenesmus and high fever. With cases of the serous type, with twenty or thirty large movements a day, it is often a question whether it is wise to administer a laxative. When mucus and blood appear in the stools, castor oil should be given and persisted in, even at the expense of some nausea and vomiting. Astringents, so much used in the past, are irrational and ineffective. Bismuth either alone or with some simple adjuvant, is today the most commonly used drug in summer diarrhea. Opium is contraindicated in the first stages of acute diarrhea, before the intestinal canal has been freed from decomposing matter; when the passages are infrequent or of bad odor; when there is a high temperature or cerebral symptoms are present, and when its use is followed by increase of temperature or the passages become more offensive. It is indicated when the passages are very frequent with pain; when the passages are excessively frequent, large, and watery; in dysenteric diarrhea, in which case it should be preceded by castor oil or a saline; in late stages with small frequent, nagging passages, and when the passages consist largely of undigested food, and the bowels act soon after the food is taken into the stomach.

2. Obstetrical Paralysis.—T. T. Thomas details his reasons for believing that most obstetrical palsies are of shoulder joint origin, as follows: In all of his cases in which the parents could recall the facts, the testimony was that following birth the child cried violently when the affected shoulder was manipulated. There were no abnormal electrical reactions in any of his cases. All of those without subluxation ended in complete recovery, except one with some restriction of abduction, and external rotation at the shoulder and an old injury at the elbow, and another about six months old, which is rapidly improving. All of the author's cases in which there seemed to be a permanent palsy, showed posterior subluxation of the shoulder joint. The chief evidence supporting the plexus theory is that obtained at operation on the plexus, all of which can be explained by the joint lesion, except the actual rupture of the roots found in a few cases which need further confirmation. The frequent occurrence of posterior subluxation of the shoulder joint was not taken into account by those most favorable to the plexus theory.

The presence of the bent-down condition of the acromion, in the author's opinion, will establish the occurrence of the subluxation at birth and therefore the dependence of the palsy upon the joint lesion. Since the roots of the plexus are all mixed motor and sensory nerves, sensation should be frequently and seriously disturbed if the cause is a rupture of the plexus, yet sensation is rarely disturbed. The Duchenne-Erb type of paralysis is generally agreed to be common to the frequent adult cases and the obstetrical palsies. The plexus lesion and the muscles paralyzed are agreed to be the same in both groups, yet the very frequent posterior subluxation in the obstetrical palsies accounted for by the effects of the paralysis, never occurs in the adult cases. Why not the same effect from the same paralysis in both groups? It is well known that traumatic dislocations of the shoulder frequently precede the paralysis in the adult cases, yet according to the present-day supporters of the plexus theory, the dislocation in the children always follows and is due to the paralysis. Why this important difference? The establishment of a traumatic origin at birth would clear up all the difficulty. Duchenne, who first described obstetrical palsies and ascribed them to injuries of the brachial plexus, found these posterior dislocations frequently associated. He said that many of them were due to manipulations of the physician during delivery—*i. e.*, they were traumatic in origin and occurred at birth. In the author's opinion the plexus theory is the greatest obstacle to the complete recovery of most of these cases, and if these dislocations were recognized at birth and completely reduced there would be few permanent obstetrical palsies.

3. Transplantation of a Testicle from the Dead to the Living Body.—G. F. Lydston, believing that obstinate chronic skin diseases, notably psoriasis, were a promising field for the therapeutic administration of the sex gland hormone via implantation implanted in the right scrotal sac of a man suffering from psoriasis, a testicle—with the epididymis excised—removed from an apparently healthy subject about twenty-one years of age, dead thirty hours before from contact with a live wire. The operation was done ten hours after removal of the testis from the dead subject—*i. e.*, forty hours after death. The postoperative course was uneventful. The wound healed by primary union, and there was very little swelling about the site of the implantation. The highest temperature recorded was 100° F. On the third day after the implantation improvement was noted in the psoriasis. The eighth day after the operation the lesions were so improved that they could scarcely be recognized as psoriasis.

2. Diet and the Toxicity of Substances Acting on Liver or Kidney.—E. L. Opie and L. B. Alford conclude that the toxicity of phosphorus which causes fatty degeneration of the liver is greater in animals which have received a diet of meat than those which have received diets consisting in large part of carbohydrates or of fat. Animals on a diet rich in carbohydrates are much less susceptible to nephritis produced by potassium chromate and uranium nitrate than animals on a diet consisting of meat or of fat. A diet of meat increases the toxicity of potassium chromate, which produces necrosis of the convoluted tubules of the kidney. A diet consisting of fat increases the toxicity of uranium nitrate, which alters the loop of Henle and produces nephritis.

4. Hay Fever.—R. C. Lowdermilk reports his experience with pollen toxin in the treatment of hay-fever. The toxin was prepared from a mixed pollen of species of ambrosia and solidago ground up with fine sand and suspended in salt solution. The fluid was pipetted off, centrifuged and sealed in glass ampules, each containing 1 c.c. For convenience the unit suggested by previous workers was used—namely, the quantity of toxin extracted from one microgram of pollen. Each cubic centimeter or ampule contained 10,000 units. From the stock solution two serial decimal dilutions were made, containing 1,000 and 100 units to the cubic centimeter, respectively. By using a tuberculin syringe graduated in hundredths of a cubic centimeter it was possible to administer doses containing any desired number of units, while the total volume of the dose never exceeded 1 c.c. The site of injection was painted with tincture of iodine and the injection was made subcutaneously in the usual manner. In no case was there any serious trouble at the site of injection. The dosage was determined by the nature and state of the reaction. The interval between doses was from five to eight days at first, but this was later reduced to one or two days, depending upon the time the reaction of the previous dose took to subside. In three patients who had long suffered from the disease, the treatment was begun about three months after the time of the annual onset and all obtained immunity after from six to eight doses had been received. In sixteen patients who had been treated after the annual onset of the attack thirteen were cured. The three not benefited began treatment more than a month after the onset of the symptoms. The reaction from the toxin is described as follows: It begins in from one-half to two hours with the exaggeration of the usual symptoms of an attack; sneezing, lacrymation, itching of the eyes, cough, dyspnea in asthmatic subjects and sometimes edema and urticaria. In one of the cases mentioned the reaction was very severe, but terminated suddenly after eighteen hours with no ill after-effects. In all cases complicated with a bacterial infection, injections of autogenous vaccines were given, sometimes following and sometimes alternating with the toxin.

6. The Leucemias under Benzol.—S. W. Sappington and W. A. Pearson report that in a case of chronic myeloid leucemia under benzol treated previously and concurrently with Roentgen rays, the leucocyte-count remains relatively low, though the formula is changed in favor of large mononuclears. The spleen remains the same size, but the patient generally is improved. The patient has been under observation two years. In a case of chronic lymphatic leucemia, benzol without roentgen assistance restored the white count to normal. Later roentgen rays were used for a short period. The patient has now been without benzol or roentgen rays for six months, yet the leucocyte-count remains low and almost within normal limits. The formula, however, has returned to a high percentage of lymphocytes. The spleen did not diminish in size, and is now further enlarged. The patient has been under observation one

year. In a case of acute leucemia benzol seemed to have had no effect one way or the other on the blood or the size of the spleen. The necropsy findings were typical of acute leucemia; there were no liver necroses or damaging effects of benzol apparent. Metabolism studies did not reveal any marked losses.

7. Cholesterin Content of the Blood in the Diagnosis of Cholelithiasis.—E. Henes, Jr., points out that almost all gallstones are formed largely, if not entirely, of cholesterin. A hypercholesterinemia seems to be the fundamental and primary etiologic factor in the formation of gallstones, and this hypercholesterinemia is easily determined. In cases of cholelithiasis without fever, a hypercholesterinemia is invariably found. Conditions simulating cholelithiasis can be differentiated therefrom by a cholesterin-serum determination. Particularly does this apply in differentiating ulcus duodeni from cholelithiasis. The hypercholesterinemia of cholelithiasis persists for a considerable length of time after the operative removal of the stones. Operation without removal of the bladder apparently does not free the patient from the probability of subsequent stone formation.

1. Hygienic Aspects of Coalmining.—F. Shufflebotham states that miners' nystagmus seldom occurs before the age of 25, and not usually before a miner has worked for ten years under ground. One is not dealing with a disease localized to the eyes, but with a general disease, one symptom of which is oscillation of the eyeballs. There may be and generally are symptoms such as headache, nausea, attacks of giddiness, muscular tremors, and twitching of the muscles in different parts of the body, especially the muscles of the eyelids, face, and neck; neurasthenia may be a prominent symptom, with its associated conditions, such as a quickened pulse, exaggerated reflexes, increased vasomotor irritability, sleeplessness, and nervous depression. All these symptoms may be present in any given case of miners' nystagmus, but in many cases some only of the symptoms are present, and at given times the prominent symptoms, the oscillation of the eyeballs, may actually be absent, although the patient is undoubtedly suffering from the disease which one knows as miners' nystagmus. The commonest complaint associated with miners' nystagmus is the jumping about or the flickering of the lights in the pit or the gas lights on the surface. The four most important factors in miners' nystagmus are: (1) Defective illumination in the mine caused by the low candle power of the safety lamp; (2) the peculiar cramped position in which miners work, especially the holers and other workers employed at the coal face; (3) the refractive errors found among the miners themselves; and (4) the frequent injuries which miners sustain during their employment, and more especially injuries to the eye itself; but it cannot be said in any case that miners' nystagmus can be caused by any one of these conditions alone, and the real truth probably lies in the fact that the onset of the disease is due to a combination of circumstances. The only hope of diminishing the number of cases of miners' nystagmus is by improving the illumination of the mines, and in the author's opinion it should be obligatory on colliery owners to supply better illumination along the roadways and at the working face, so that the incidence of this disease in the future shall be materially diminished.

2. One Thousand Consecutive Abdominal Operations.—A. E. Giles reviews a series of 1,000 consecutive abdominal operations performed by him at the Prince of Wales's Hospital, Tottenham. There was a marked drop in the mortality of the last 500 as compared with the first 500 cases, the percentage being 3.4 in the later series and 5.2 in the earlier. The improvement may be attributed to three principal causes: (1) The personal factor of experience; (2) a higher standard of asepsis; (3) improved technique, such as the systematic use of gloves during operation and the introduction of the iodine method for the preparation of the skin in the area of the operation.

3. The Pituitary Gland and the Sella Turcica.—E. G. Fearnsides points out that in acromegaly there is always some definite evidence of an increase in size of the pituitary fossa. Cushing has divided the enlargements of the sella turcica occurring with primary growths arising from the pituitary body itself into three types: (1) Those associated with thickening of the clinoid processes and dorsum sella; (2) those showing thinning from pressure absorption of these parts; and (3) those showing more or less destruction of all the outlines of this region, and he states that tumors arising from the pituitary stalk in the interpeduncular region and situated above the sella—the so-called superimposed tumors—give rise to changes in the sella turcica only after they have reached a considerable size. In addition to the changes in general metabolism, disease processes arising in the pituitary body owing to the anatomical relations of the gland to the optic tracts, to the third cranial nerves, and to the crura cerebri, early give rise to the localizing nervous signs. The appearance of these, together with the changes known to occur when the activities of the pituitary body are deranged or with radiographic changes in the conformation of the sella turcica, renders diagnosis of pituitary disorder more certain than of the other intracranial conditions. In doubtful cases a change in the size and shape of the sella turcica as seen in the *x*-ray plate is the most certain evidence of pituitary disorders.

5. Pituitary Tumors.—W. Johnson reports four cases of pituitary tumor in which a pathological examination was made, and in two of which the degenerative changes in the optic tracts were also studied. The only change which was possible to demonstrate in the visual fibers as the result of the lesion of the optic chiasma which had caused eye symptoms in both of the latter cases for upwards of two years was a degeneration in the optic tracts. This degeneration was not found extending further back than the primary optic ganglia. The amount of change present in one case was more than was indicated by the visual loss. The statement that certain optic fibers reach the occipital cortex without relaying in the cell stations in the primary optic ganglia would appear to be refuted by the fact that no degeneration was found in the optic radiations and the fibers entering the calcarine cortex. Finally both cases showed that the uncrossed visual fibers tended to occupy the outer and lower portion of the optic tracts.

3. Hemostasis by Application of Living Tissue.—Sir Victor Horsley states that it is difficult to stop bleeding and hemorrhagic oozing from soft tissues except by the employment of a ligature or pressure with a gauze tampon, or by irrigation with hot liquid. For a long time the author employed amadou for this purpose in experimental investigations where asepsis was not required, and with good results, as it adhered well to the bleeding point. To obtain, however, the same result in aseptic operations is not so simple. The factors which had to be obtained were asepticity, adhesiveness, and thrombokinesis. It occurred to the author that probably the best material would be living vascular tissue, that from the injured surface of a cut fragment of muscle. In all probability, thrombokinetic processes would most readily start, not merely on account of the plasma and plasmatic corpuscles of the tissue, but also the thrombokinetic by-products in the effused blood and the development of the so-called blood platelets. Such a fragment of the animal's own muscle offered all these advantages, and also asepticity. If the bleeding point, for example, from the cut surface of the brain, liver, or any soft tissue, be gently pressed with gauze, and this instantly be replaced by a piece of living muscle, and pressure be again applied from fifteen to twenty seconds, it will be found that the muscle fragment closely adheres to the tissue to which it is applied.

4. Radium Therapy by Means of Emanation Needles.—W. C. Stevenson describes an economical method of employing radium in the treatment of malignant growths by means of hollow needles enclosing glass capillary tubes containing the radium emanation. The needles are ordinary steel serum needles. Their external diameter is 1.4 mm., their thickness, 0.3 mm., and the diameter of their bore, 0.8 mm. The glass capillaries have as maximum dimension an external diameter of about 0.76 mm., an internal diameter of 0.46 mm., and a thickness of 0.15 mm. One cm. of these capillaries would theoretically be capable of holding the emanation equilibrium of about three grams of radium at atmospheric pressure. The emanation needles have decided advantages. They are an economical method of using the therapeutic properties of radium. Clinically they are easily and safely employed, without an anesthetic or the use of an operating theater. They admit of very accurate dosage. They permit a tumor to be subdivided into areas which can be efficiently treated by small quantities of emanation. The collection of needles reach the deep parts, and radiate them as uniformly as it is possible to do at the surface, provided that the sources of radiation are within range of the soft rays—that is, the needles are not more than 3 cm. apart, which is about the average distance of human tissues traversed by these soft rays.

5. X-ray Treatment of Tuberculous Glands.—H. Mowat points out that the great advantage of the *x*-ray treatment of tuberculous glands is that it saves the patient the unpleasantness of undergoing in many instances a severe operation. The results are equally satisfactory whether the glands are large or small, numerous or scanty, superficial or deep, because by means of filters the penetrating power of the rays can be controlled and by using hard tubes those glands deeply situated can be reached. Even when the glands have broken down and are fungating great improvement results, as is noted in one of the author's cases, which unfortunately ceased to attend the hospital when showing marked improvement. It is advisable to use a hard *x*-ray tube, and it is also necessary to filter the rays through aluminum or felt; the author generally filters through 1.5 mm. of aluminum. The current should range from 2 to 3 milliamperemeter, and the rays should be applied directly to the affected parts, a suitable lead glass screen of the requisite size being used. The exposure given should be, at any rate, one full Sabouraud dose, but in some cases it is advisable to exceed this by about a quarter. Cases may be treated twice a week. Most of those reported were only seen once a week or even less frequently, owing to the difficulty of persuading the patients to come to the hospital, had the attendances been more regular even more rapid cures would have resulted.

Berliner klinische Wochenschrift.

June 29, 1914.

Laminectomy and Spondylitic Paralyses.—Tietze refers to the recent work of Albee in connection with tuberculosis of the vertebræ in complimentary terms and states that he is beginning to use it. He makes the claim, however, that Henle introduced the same method in Germany about two years ago without being in the least aware of Albee's priority. He would, therefore, term the procedure the Albee-Henle method. The point of interest in this connection is that Albee has used his method a few times in connection with the radical operation for spondylitic paralyses. The latter are for the most part spastic in character, and are due to compression of the cord. They sometimes become changed to flaccid palsies. The compression may be due to several local causes which narrow the canal, as fracture of a vertebra, in which extension of the spine may suffice for treatment. Conditions which require laminectomy, are peripachymeningitis, spondylitis, tuberculous abscesses, etc. Tietze was the pioneer surgeon to perform Foerster's operation of division of the posterior roots for spastic paralysis of cerebral origin, which required a preliminary laminectomy, but in this type there was no necessary compression of the cord. In the present case decompression of the cord necesitates laminectomy. The spastic paralyses vanish with the decomposition. In connection with the latter operation the local tuberculosis commonly present requires extirpation, just as in ordinary Pott's, without compression and spastic paralysis. It is in this connection that Albee's method comes in place to restore the mechanical functions of the spine by implanting a piece of bone.

Communication of Hodgkin's Disease to Guinea Pigs.—Schaeffer prefers to use for this condition the term lymphogranulomatosis, once held to be a malignant tumor formation, than a species of granuloma, with further suspicion of a tuberculous origin. The author has injected matter from a Hodgkin's nodule into a mouse and the animal developed a local and general granulomatosis. Aside from intracellular acid-fast bacilli of unknown character, no possible living cause could be detected, although certain morphological features may be characteristic, as giant cells of the Sternberg-Pattauf type. The supposed Much type of granulated

tubercle bacillus was quite absent, but the acid-fast bacillus already mentioned could not be distinguished from Koch's bacillus, and may explain the presence of the giant cells. The author does not commit himself to a theory of paratuberculosis, but marshals all the evidence in its favor, and thinks the tuberculous theory accounts well for most of the facts.

Münchener medizinische Wochenschrift.

June 23, 1914.

Chronic Ankylosis of the Vertebral Column.—Fraenkel claims that it is no longer justifiable to speak of the von Bechterew or Marie-Strüppell disease. We know today that we are dealing with an anatomical process which may involve other joints. This is often enough in evidence through the changes in the ligamentous structures, but cases are not rare in which we may see a rigid spine without these particular manifestations. In this second group of cases the sole lesion is ossification of the cartilages between the joints of the articulating processes. This essential lesion shows that we are dealing with a pure joint affection such as occurs in other joints, as the sacroiliac symphisis. This stiffening of the spinal column must be distinguished from spondylitis deformans, which, originating in the intraosseous disks causes the vertebræ to lose their alignment, while marginal exostoses appear on the vertebræ and by pressure upon the adjacent transverse processes give rise to a special type of immobilization. Yet in this condition the joint surfaces are intact. The prognoses of these two affections is very different, for, while in spondylitis deformans it is favorable, the reverse is the case with joint ankylosis type, or, as some term it, "spondylarthritis ankyloproctia."

Hemiplegia in the Course of Typhoid with Recovery.—Wulf remarks that acute and chronic infectious diseases predispose to affections of the nervous system, and this is as true for intoxications (lead, alcohol). It is only rarely that these causes proceed so far as to determine focal intracranial lesions (hemorrhage, thromboses, emboli, abscess, etc.), in comparison with the frequent participation of the meninges. The same contrast holds good for the spine. The peripheral nerves are highly predisposed to participation in infections and intoxications. Summary of the author's solitary case is as follows: A man, aged forty-four, admitted for abdominal typhus, showed in the third week hemiplegia, which readily disappeared without the appearance of complications. The lesion should have been either a simple hemorrhage or embolism with softening. No point for the production of an embolus could be found, so that one of the intestinal ulcers was temporarily accused. Another explanation hardly justifiable was that of a typhoid degeneration of the blood vessels. Lumbar puncture seemed to exclude thrombosis and abscess, and also encephalitis, which latter can manifest itself as an apoplectic attack with complete recovery.

Deutsche medizinische Wochenschrift.

June 14, 1914.

Influence of Iodine on the Capacity for Procreation.—Loeb and Zöppritz overhaul the sparse literature of this subject. In 1820 Coindet announced that the drug could dry up the milk secretion and cause atrophy of the breasts. This teaching was incorporated in most of the pharmacologies, although Harnack claimed that the stomach was primarily affected. Hugo Schulz taught that iodine caused menstrual disturbances and the legend also was fostered that the same drug caused atrophy of the testicles and impotence. This belief can be traced back to Hufeland. Scanzoni and others placed iodine and its combinations among the abortifacients. Experimental data are few, and the authors have sought to add to them, using the mouse as a subject. The animals retained all the normal libido and ability to copulate under iodine feeding, but no pregnancies resulted. Both sexes were undoubtedly sterile. When iodine was removed from the diet, pregnancies at once followed; when given to pregnant animals, abortion resulted. The general health was not affected in these cases, nor was the nutrition. The conclusion must invariably be that no measurement of iodine medication is possible, unless the thyroid can be isolated; for the drug may activate the iodine in this gland.

Cause of Variola in Pure Culture.—Seiffert has sought to test the claims of Fernet and others concerning the preparation of pure cultures of the as yet hypothetical cause of smallpox. He concludes as follows: His own work causes him to regard that of Fornet as defective, while proof of the cultivation of the said germ is as yet wanting. The author's work, in brief, gave negative results throughout. In addition, sources of possible error continually cropped out, and these alone were sufficient to cause him to abandon Fornet's line of work. There is no evidence that a cultivation of any sort was present. Neither Fornet nor anyone else has as yet made headway in this direction, and there is no hope that ordinary commercial vaccine will be supplanted by cultures.

Vertebral Metastases after Hypernephroma.—Harttung shows that the bone metastases are noted before the tumor. They are osteoclastic in type. It is well known that true primary malignancy of the vertebræ is very rare. He alludes to bone metastases following cancer of the stomach, but appears to be silent on thyreogenous bone malignancy. The author's one case occurred in an elderly woman, in whom the entire vertebral column was affected, giving it a Gibbons curve. Naturally, radiography was indispensable for diagnosis and showed extensive destruction of the dorsal vertebræ between the second and tenth, inclusive. The existence of a malignant growth in the body was at once surmised, and the results of a simple urinary examination were sufficient to accuse the kidney. Laminectomy did not expose any tumor masses, but the pressure within the spinal canal was relieved and the pain was abolished. The patient lived but a short time. The tumor was not of the embryonal type which attacks young children, but was of nephrogenous origin. It lay encapsuled, occupying the lower pole of a kidney, and was of the size of a small fist. No microscopic data are given, but there was evidence of a true metastasis.

Fracture of an Incisor Tooth; Dental Cyst.—P. Turner reports the case of a patient, aged 12 years, who had a fall two years ago and fractured one of the right upper incisor teeth. Three months ago a swelling of the right upper jaw was noticed. This had increased slightly since then. There was a well-marked bulging forward of the facial aspect of the right superior maxilla. Digital pressure in the region of the canine fossa gave typical "egg-shell crackling." The hard palate on the right side was depressed, and there was a widening of the anterior part of the alveolar process. There was no exophthalmos and no nasal obstruction or discharge from the right nostril. The right central incisor was fractured and the pulp exposed; the right temporary canine had not been shed and was loose. A skiagram showed that the pulp cavity of the fractured tooth was exposed, and that the apex, which was imperfectly formed, projected into the cyst cavity.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

Life Insurance and Arterial Disease.—Dr. Brandreth Symonds, Chief Medical Director of the Mutual Life Insurance Company of New York, says in a letter to Dr. Louis Faugères Bishop, published in the latter's work on arteriosclerosis, that in the etiology of this condition one small circumstance indicates that a tendency to cerebral arterial diseases may be hereditary. In studying the influence of apoplexy or paralysis in the family record, he has found that the presence of two or more cases in the family history materially increased the mortality. In these cases heredity, infection, or environment seemed to have a decided effect in determining the mode of exit, for 21 per cent. of the deaths were due to apoplexy or paralysis, as compared to 8 per cent. among all men. Symonds is convinced that overeating is a more important factor in the causation of arterial disease, probably more so than the overuse of alcohol. The exact method by which overeating operates as a cause of arterial diseases cannot be stated at present, and it may operate in a number of differyent ways. He states that a great deal of reliance should be placed on the measurement of the blood pressure when taken by experienced men.

Five Years' Work of the Insurance Committee in Germany.—In 1895 a commission of three German physicians and three medical representatives of German insurance societies was formed, and the first session was held in February, 1896. In 1904, Medical Director Handel being deceased, the author, Dr. Samwer of Gotha, was elected to succeed him. He had as colleagues three medical directors and three official sanitary experts, and for four years these colleagues took part in all problems connected with the simplification of insurance medicine. In 1908 the commission was dissolved temporarily and its work was taken over by the German War Department. In January, 1909, the commission was revived and given until May of the same year to report. Since that period, with some changes of personnel, the commission has been convened at intervals and reports have been made. The changes of personnel were not arbitrarily made, but each member was elected for a given term.

In the five years' period which began in 1909 fifteen sessions were held in various parts of the Empire, and were well attended. About 400 complaints were heard, of which two-thirds came from the outside medical men and one-third from the medical directors of companies.

It is manifestly impracticable to reproduce the work of the commission, even in abstract. Certain precedents and decisions were determined from time to time. Thus the medical director can remove an examiner but the latter can appeal to the standing committee. An insurance society may order an examination by a second examiner, the proceedings to be confidential. If several examiners are available at one place, the local agent can leave the choice to the prospective risk.

Much space is devoted to the examiner's fee, the conditions affecting the examiner, etc. The fee for an examination at the applicant's home, whether the journey is a special one or undertaken in common with a journey for another purpose; whether special care in examinations is deemed requisite—all such points enter into the question to a surprising extent. For example, while no extra fee can be claimed for a superficial examination of the ear, 3 marks can be charged, should the ear be filled with wax, for removing the latter.

As a result of the work of the commission from 1909 to 1912, covering almost four years, a treaty has been worked out which gives the duties and privileges of the various parties concerned. We find no mention of the permanence of these regulations, which doubtless will require but few modifications.—*Blätter für Vertrauensärzte der Lebensversicherung*, March-April, 1914.

The Comparative Uselessness of Fehling's Solution in Testing for Sugar.—In a discussion on "Diabetes" before the Life Assurance Medical Officers' Association of Great Britain on March 4, 1914, Dr. Cammidge said that he had given up the use of Fehling's solution for a good many years. In his opinion the most satisfactory, the most reliable, and the most easily used test was Benedict's. Among its advantages were, firstly, that it was a single solution, and did not require mixing before use. Secondly, it kept indefinitely. Thirdly, it contained no caustic alkali, so was less difficult to handle and boil. Fourthly, not more than eight or ten drops must be used for the test, consequently there was no smell on boiling. Fifthly, the result was absolutely distinct and was quite as good by gaslight as it was by daylight. Sixthly, it was rather more sensitive than Fehling's so that if no reaction was obtained it might be concluded that the urine was sugar free. Cammidge was of the opinion that it was admirably adapted for life assurance work and that if it were regularly used, many of the mistakes one constantly saw would be avoided.

The Significance of Temporary Glycosuria.—Dr. Otto May read a paper on March 4 before the Life Assurance Medical Officers' Association of Great Britain dealing with the above matter. He pointed out that a question of perennial interest in life assurance work was the prognostic significance of temporary glycosuria. By this term was meant the discovery during the examination of the presence of dextrose in the urine of an apparently healthy person, while a further examination after a variable period failed to reveal its presence, although the proponent was on his usual diet. The practical point on which information was needed was: What proportion of these cases ultimately developed into true diabetes. In other words, was a medical examiner justified in recommending such a life for acceptance at first-class rates or was the risk of the ultimate development of diabetes mellitus sufficiently great to warrant the proposal being considered only on special terms?

May's conclusions on "temporary glycosuria" were summarized as follows: 1. True "alimentary" glycosuria, *i.e.* glycosuria in a healthy person consequent on excessive ingestion of sugar was a very rare occurrence. 2. Most cases of temporary glycosuria were due to a temporary or permanent lowering of the "assimilation limit" of the organism for sugar. 3. If practicable, an attempt should be be made to determine this "limit" by test-meals of sugar. If this limit was about normal, the life might be accepted at tabular rates or with a slight loading; if, on the other hand, the "limit" was definitely lowered, the life should be declined or accepted only at considerably increased rates.

Book Reviews.

DEVELOPMENT AND ANATOMY OF THE NASAL ACCESSORY SINUSES IN MAN. Observations based on two hundred and ninety lateral nasal walls, showing the various stages and types of development of the accessory sinus areas from the sixtieth day of fetal life to advanced maturity. By WARREN B. DAVIS, M.D., Corinna Borden Keen Research Fellow of Jefferson Medical College; Assistant Demonstrator of Anatomy in the Daniel Baugh Institute of Anatomy, Philadelphia. From the Laboratories of the Friedrichshain Krankenhaus, Berlin, Germany, and the Daniel Baugh Institute of Anatomy, Philadelphia. Drawings by Dorothy Peters. Octavo of 172 pages with 57 original illustrations. Cloth. Price $3.50 net. Philadelphia and London: W. B. Saunders Co., 1914.

THIS work is based upon the careful study of such a large series of specimens that the ultimate conclusions are necessarily worthy to be considered as representing the proper conception of the average or normal conformation of these areas. As the author says, the literature covering this subject is abundant, and yet there is certainly a place for this work; for the combination of text and plates furnishes one of the most complete if not the *most* complete presentation of this subject extant. The relations and the conformation of the various sinuses are very imperfectly understood by the average practitioner, and probably it would not be far from the truth to include in this category the average surgeon also; but a perusal of this book, together with a study of its truly magnificent plates, should put a speedy end to all confusion as to the anatomy of these parts. Paper and press-work are of a commensurate high quality, so that the book is one of which the publishers as well as the author may well be proud.

COMMUNICABLE DISEASES: An Analysis of the Laws and Regulations for the Control Thereof in Force in the United States. By J. W. KERR, Assistant Surgeon General and A. A. MOLL, A.B. Prepared by Direction of the Surgeon General. Treasury Department, United States Public Health Service. Washington: Government Printing Office, 1914.

THIS volume is a valuable contribution to medical literature and should be of especial interest to public health officers, pediatricians, and school medical inspectors. It is a thorough digest of all federal and State laws and regulations pertaining to the control of communicable diseases. An idea of the comprehensive nature of its subject matter may be gleaned from a summary of a few of the topics discussed, such as federal laws pertaining to foreign commerce, railway sanitation, biological products, etc.; State laws on quarantine, placarding, hospitals, disinfections, disease carriers, hotels, school sanitation, jails, laundries, barber shops, etc. All appendix contains the text of court decisions on many subjects with reference to the control of communicable diseases. The text of all State and federal laws on this subject is given in full.

PHARMACOLOGY—CLINICAL AND EXPERIMENTAL. A Groundwork of Medical Treatment, being a Textbook for Students and Physicians. By Dr. HANS H. MEYER, of Vienna, and Dr. R. GOTTLIEB, of Heidelberg, Professors of Pharmacology. Authorized translation into English by JOHN TAYLOR HALSEY, M.D., Professor of Pharmacology, Therapeutics, and Clinical Medicine, Tulane University. With 65 text illustrations, 7 in colors. Price $6.00. Philadelphia and London: J. B. Lippincott Company, 1914.

THE experimental and clinical aspects of modern pharmacology are admirably presented in this volume, which is probably the latest and most complete treatise on this subject that has been written. The authors divide drugs into two classes—organotropic and etiotropic—and describe and analyze the organotropic pharmacological actions separately for each organ or functional system. There are separate chapters on the pharmacology of the motor nerve endings, of the central nervous system, of the sensory nerve endings, of the vegetative nervous systems of the eye, of the digestion, of the reproductive organs, of the circulation, of the respiratory system, of the renal function, of the secretion of sweat, of the metabolism, of the muscles, of the blood, and of heat regulation, of inflammation; and on etiotropic agents, on factors influencing pharmacological reactions. The text is elucidated by a large number of diagrams and graphic formulæ, and full references to the literature are appended at the end of each chapter. The therapeutic indications of the different drugs described are discussed in detail. The book is highly interesting and clearly written, and the translation is an excellent one.

THE OCCUPATIONAL DISEASES. Their Causation, Symptoms, Treatment, and Prevention. By W. GILMAN THOMPSON, M.D., Professor of Medicine, University Medical College in New York City; Visiting Physician to Bellevue Hospital. Illustrated. New York and London: D. Appleton & Company, 1914.

ALTHOUGH the professional neuroses and various diseases incidental to the victim's occupation, such as lead poisoning, phosphorus necrosis, mercurial tremor, pneumonoconiosis, caisson disease, etc., have long been recognized and been made the subject of considerable study, the literature of the subject is not extensive and confined chiefly to monographs. Of late years, however, some comprehensive treatises have appeared in Germany and Great Britain. The book before us, by Dr. Thompson, is the first of its kind in this country. It comes at a very opportune season, at a time when great concern is being taken in the condition of the worker and when compulsory workingmen's insurance is being put in force in many States. The author's object in writing this work has been particularly to meet the needs of American practitioners of medicine, as well as of those of the laity whose professional or philanthropic interests require a comprehensive summary of the nature and prevalence of the occupational hazards as they obtain in this country.

Part I comprises history, classification, general pathology, and etiology. It is pointed out that the kind of work and the conditions under which such work is done have a distinct influence upon health and are instrumental in favoring the progress of many diseases. For instance, there is an obvious relationship between tuberculosis and the manner of work in which a person is employed and the conditions under which he works. The author draws attention to the good effects which have followed compulsory reporting of occupational diseases in England and notes that a similar system has been instituted in six States of this country. He recommends its general adoption.

Part II is devoted to prophylaxis. The subject of workingmen's insurance against occupational disease is discussed and it is pointed out that in Germany this scheme has met with great success. With regard to effective ventilation of factories and workrooms—a most important factor in preserving the workers in good health—Dr. Thompson is inclined, when it is feasible, to rely on the open window. Emphasis is placed upon the need for the workingman and workingwoman to pay due attention to personal hygiene. That part of the work dealing with treatment is full and useful.

Part III discusses diseases due to irritant substances and shows that with regard to the protection against industrial lead poisoning legislation in this country is woefully lacking. Referring to methyl alcohol, the author insists that stringent laws should be passed forbidding its employment in such a form that it may be dangerous to health or life. Part IV is devoted to a consideration of diseases due to harmful environment. Part V deals with special occupational diseases, and the author notes that neurasthenia is very common among many classes of workers. Part VI treats of the influence of special conditions on the occupational diseases. The question of alcoholism is debated at some length and attention is also drawn to the fact that non-alcoholic stimulants are often abused by workers. Part VII is concerned with miscellaneous occupational diseases grouped by industries not included in the foregoing classification. The mining industry is discussed exhaustively and a considerable amount of space is given to pottery making, china, and porcelain. At the end of the book are some valuable appendices.

Although medical writers of this country have been late in the field in furnishing literature regarding diseases of occupation, Dr. Thompson by the publication of his book has entirely removed any reproach that might attach to them for this omission. The work is the most complete, so far as the reviewer is aware, of any on the subject in the English language. It is well arranged, excellently printed, and clearly illustrated. It is a valuable work from both the medical and the sociological point of view, and the author is to be congratulated upon the production of so comprehensive and practical a treatise in which the crudities almost inseparable from pioneer work are conspicuously absent.

Society Reports.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Thirty-first Annual Meeting, Held at Atlantic City, June 19 and 20, 1914.

THE PRESIDENT, DR. JAMES M. ANDERS OF PHILADELPHIA, IN THE CHAIR.

Friday, June 19—First Day.

FOLLOWING the invocation by Rev. Henry Merle Mellin of the First Presbyterian Church, Mayor William Riddle welcomed the members of the association.

President's Address.—Dr. JAMES M. ANDERS of Philadelphia made this address. After making grateful acknowledgment of the signal honor which had been bestowed upon him he said that the traditions of the American Climatological Association were highly creditable and its record for scientific achievement was equally noteworthy. It was a recognized fact that the massed and combined intelligence of a large body of professional men was seldom wrong. On the other hand, the presentation of the views of an individual member often failed to be convincing as contrasted with the instinct of either a people or profession. There were certain problems which seemed to him to demand attention. First was the climate of America, a climate of great variety, both health giving and health destroying, according to its organization as well as special characteristics at different seasons and in different localities. Few persons could give up an inherited belief that some connection, manifestly not a feeble one, existed between climate and the public health. It remained for future scientific investigation and study to establish between the two with greater precision the relationships actually existing. The unique records of absolute heat and cold, as well as aridity enjoyed by this country, were particularly noteworthy. It was not only the legitimate function of the association to investigate the various meteorological elements and conditions affecting the state of the climate, both local and general, but also to study such questions as the influence of special climates and particularly the seasons of the year, as predisposing factors in the causation of disease, as well as the therapeutic use of the different weathers to be found in the United States and Canada. It was especially desirable to investigate further into the modifications of climate and weather in small localities since these were often of first-rate importance as aids in the treatment of certain diseases. It would be both profitable and interesting to draw comparisons between their climate and that of other countries. John Burroughs had said that an American resident in England was reported as saying that the English had an atmosphere, but no climate, and then added: "We certainly have a climate, a two-edged one that cuts both ways, threatening us with sunstroke on the one hand and frostbite on the other, but we have no atmosphere to speak of in New York and New England, except now and then during the dog-days, or the fitful and uncertain Indian summer." He continued: "An atmosphere, the quality of tone and mellowness in the near distance, is the product of a more humid climate. Hence, as we go south from New York, the atmosphere effects become more rich and varied, until on reaching the Potomac you find an atmosphere and a climate." Here Walt Whitman saw the full moon "Pour down night's nimbus floods." The association should keep the medical profession's attention constantly fixed on hydrotherapy, a subject that had been too scantily considered by its members in the past. Climatology and hydrotherapy should form a definite branch of medicine, and each of us should be willing and eager to assume an individual share in the contributions and discussions. He said that he trusted to the importance of the subject to maintain a lively interest in this organization which should be capable of exerting a potential influence. The American Climatological Association had been steadily winning its way in the medical profession of the United States and Canada. At no previous time had it been so deeply imbued with the importance of giving serious attention to the various physical methods of the treatment of disease as at the present day. The founders of the association clearly recognized the true relationship of medicine to public health: as a national organization they should not desire to ignore sociological and sanitary problems in so far as they were related to hygiene, climate, and hydrotherapy. In regard to the many public questions affecting the health and welfare of the profession and laity alike, the association should in the future make a creditable showing. Granted the recognition of the true place and importance of climatology and hydrotherapy, Dr. Anders said he was not averse to changing the name of the organization to that of the "American Medical Association of Climatologists and Clinicians," or to calling upon those specially interested in these lines to share in an extension of the clinical portion of their program. The association could readily adapt itself to a broadening of its field of endeavor and it should widen its boundaries. The science of medicine should strive to rid itself of vague, loose, unsystematized knowledge and should work toward a more comprehensive system.

A Memoir of the Late Dr. Egbert Le Fevre.—Dr. A. ALEXANDER SMITH of New York presented this memoir, which was read by the secretary.

The Climate of Southwestern Alberta.—Professor R. F. STUPART, director of meteorological office, Toronto, Canada, presented this communication, which was read by the secretary. Banff was situated in latitude 51 10′ on the Bow River at an altitude of 4,542 feet, well within the Rocky Mountains, and at a distance of ninety miles from the city of Calgary, which was on the prairies at an altitude of 3,389 feet, and also on the Bow River. A fully equipped meteorological station was established at Calgary in 1883. A temperature and precipitation station was established at Banff in 1890, and raised to a first-class station in 1894. In 1904 an observatory with self-recording instruments was placed on Sulphur Mountain, Banff, at an altitude of 8,030 feet, and four miles distant from the village station, the difference between the two stations being 3,500 feet. He was strongly of the opinion that the claims of Banff as a summer sanatorium were distinctly good; the winter was not so severe, and even the coldest months might be altogether desirable for many pulmonary complaints. Certainly as a pleasure resort it might be ranked with any of the places in Europe to which people flocked for ski-ing, tobogganing, and skating.

Dr. CARROLL E. EDSON of Denver, Colo., believed that in such a climate sleeping out of doors was entirely impossible and that the people afflicted with tuberculosis would shut themselves indoors and hasten their death. There they had long winters and short hours of sunshine.

Prolonged Subnormal Temperature in Tuberculosis.—Dr. ARTHUR K. STONE of Boston, Mass., presented this communication. He said that subnormal temperatures were common in this disease, but the exact cause he did not know.

Dr. CHARLES L. MINOR of Asheville, N. C., said that this was a subject that he had been much interested in. It should not be forgotten that there was one common cause of subnormal temperature in tuberculosis, the lower activity of metabolism. There should also be remembered the weakness of the patient with a low vitality; that often such a patient overexerted himself; the cold weather; the carelessness often made in taking temperatures, etc. With regard to the treatment of such cases whiskey was of great value; patients with persistent subnormal temperatures did well when given whiskey.

Dr. GEORGE W. NORRIS of Philadelphia said there was one class of cases to which attention should be called, those with essential hypotension or constitutional low arterial tension where the diastole was never 110. The study of the blood pressure should be of more value to those interested in tuberculosis. According to German writers the blood pressure readings were of little value; but according to the French writers they were of great diagnostic value.

Dr. WILLIAM LEROY DUNN of Ashveille, N. C., said that in his experience there was great disparity between the rectal and mouth temperatures in these cases; when the temperature was taken by way of the mouth the impression was that it was subnormal, but this was disproved when it was taken per rectum.

Dr. C. FOX GARDINER of Colorado Springs, Col., said that not less than 40 per cent. of the clinical thermometers were inaccurate.

Dr. JAMES ALEXANDER MILLER of New York said that there were many conditions which might give rise to prolonged low temperatures in tuberculosis, but it seemed to him that what was needed was a more careful observation. Certain observations had been made by Professor Lee of Columbia and himself with two

thermometers connected with an electric galvanometer in people with normal and subnormal temperatures and they believed that it was not wise to rely upon the rectal or mouth temperatures as shown by these instruments.

Dr. CLEAVELAND FLOYD of Boston, Mass., said that he had obtained some striking results in these patients after they had exercised, the rectal temperature going three or four degrees above the normal; following a period of rest the temperature would become normal.

Dr. CARROLL E. EDSON of Denver, Col., emphasized the importance of the clinical management of these cases; the fundamental basis had not been understood, evidently, and had not been appreciated.

The Prophylactic Value of Water Supplies and Baths, with Special Reference to Industry.—Dr. THOMAS DARLINGTON of New York City said that he had made for four years a special study of water supplies and baths with special reference to industry. It paid to safeguard against accidents, and it also paid to care for the health of the workmen, for their efficiency depended upon their health. He advised raising their health to the highest power and this could be attained by more attention being paid to the drinking water and to the baths. The use of the shower bath lessened their fatigue. Dr. Darlington called attention to "Typhoid Mary," who did not wash her hands and because of that fact spread the disease, and no one really knew just how much of typhoid fever was carried and disseminated by her.

Dr. DE LANCEY ROCHESTER of Buffalo, N. Y., called attention to a sign he once saw in school which read, "No boy belongs in school with dirty hands," and to another sign which read, "Be sure to wash your hands before you eat."

Dr. CHARLES FOX GARDINER of Colorado Springs, Colo., believed that what was just stated should apply to patients with tuberculosis as well. The cleansing of the hands should be impressed more upon the people.

Housing and Its Relation to Climate and Health.—Dr. ESTES NICHOLS of Portland, Maine, asked if in the fight for the health of the American people any association should take a greater part in the battle for better homes than the American Climatological Association. America had been very slow in recognizing the importance of housing and its relation to climate and the health of the masses. Was not the method of housing people, one home on top of another, many stories high, unnatural and unhealthy? Was climate responsible for the present conditions of housing? Was not the system of apartment houses placing a premium on the rearing of children? As climatologists should they not take a more active part in housing reform and city and town planning?

Dr. THOMAS DARLINGTON of New York City said that there was no doubt but that overcrowding lessened the resistance to disease; this was not only true in the cities, but even in camps where the sanitation was bad. To-day they had better plumbing and sanitary conditions in the cities were much improved. It was not so much marsh gas that was harmful in houses as carbondioxide; this was true particularly where there were no electric lights. With regard to the distribution of population it was a fact that 65 per cent. of the immigrants who came to New York City from Europe stayed in New York City. In many instances, even though they might buy pure food they kept it in iceboxes where there was no ice, and therefore they lacked the proper kind of food. This lack of proper food also caused a lessened resistance to disease. The lack of proper food was specially noted in reference to the girls in the eastern districts of New York City. He had seen many of these girls eating tomato salad with its nine calories when it would have been far better for them to have eaten baked beans. The real cause of disease in the tenements was overcrowding and improper food.

Dr. CHARLES FOX GARDINER of Colorado Springs emphasized the importance of proper housing of the masses. If people could be taught to live more outside and separately it certainly would lessen the spread of diseases which resulted from personal contact. The personal hygiene in the houses was of more importance than the housing itself. He spoke of some of the conditions he found in the rural districts of Connecticut, which were worse than he found in the cities of that state.

Dr. ROBERT CHILDS PATERSON of Ste. Agathe des Monts, Province of Quebec, Canada, said that if people were to live in the tenements and in outlying districts they should be provided with proper sanitary conveniences. There should be a proper and sufficient supply of drinking water in every house. The expense of course became greater. He said that north of Montreal he found that the death rate from tuberculosis was higher even than along the Canadian border. The health of the people had been undermined by their methods of life, too little food and too little ventilation. Slops and dish water were merely thrown out of the door or window and the children played around and in them. These conditions were harder to solve, in his opinion, than those surrounding the tenement population.

Dr. NATHANIEL K. WOOD of Boston, Mass., emphasized the importance of hygiene in these problems confronting us and said that the government of the United States had already shown what could be done by stamping out yellow fever and malaria during the building of the Panama Canal.

Dr. GUY HINSDALE of Hot Springs, Va., asked why the air was so pure in the country and answered that it was because the bad air was shut up in the houses.

Tuberculosis in Relation to the Atmospheric Air.—Dr. GUY HINSDALE of Hot Springs, Va., read this paper by title.

Some Unsolved and Debatable Problems in Tuberculosis.—Dr. EDWARD O. OTIS of Boston read this paper. "Die Tuberkulose hat uns lange Zeiten hindurch immer wieder Rätsel zu lösen gegeben," said a recent writer, and it was to some of these problems upon which there existed conflicting and perhaps erroneous opinions, or for which they had as yet not found satisfactory explanation. Dr. Otis first called attention to the undue emphasis placed upon the detection of physical signs in the early-diagnosis propaganda. The general practitioner had now for many years been lectured in season and out of season upon the supreme importance of the early diagnosis of tuberculosis, and he had been unmercifully berated for his dereliction in neglecting to do this, many times justly and sometimes unjustly. In his experience he found him making a diagnosis of clinical tuberculosis upon indefinite physical signs, without giving due weight to the more important evidence of clinical symptoms. The distinction between clinically active tuberculosis and local infiltration without symptoms did not seem to be always clearly comprehended. Drs. Gelien and Hammon had, it seemed to him, very justly estimated the relation between the physical signs and symptoms in making the early diagnosis when they said that "the early diagnosis of pulmonary tuberculosis is more a matter of clinical experience and judgment than of unusual skill in eliciting slight abnormalities in pulmonary physical signs." It seemed to them that in attempting to improve the diagnostic acumen of the general practitioner toward pulmonary tuberculosis more emphasis should be laid upon the observation of symptoms than upon the pulmonary examination.

Marriage and Tuberculosis.—They were doubtless familiar with the oft-asserted solemn warning of a prominent phthsiotherapist that a tuberculous husband and wife should be taught "not to procreate a race predisposed to tuberculosis." It seemed to him that this was too sweeping a statement without modifications. How did they know that children would be predisposed to tuberculosis? The recently published experiment of Brooks would appear to offer substantial proof to the contrary, reasoning from analogy. In this experiment tuberculous cows were bred to tuberculous bulls, and at birth the calves were immediately taken from their mothers and fed upon modified pasteurized milk. Of more than 200 calves thus born not one became tuberculous. Why should they not expect that children born under similar conditions and treated in the same way would show the same results? Why should not a tuberculous husband, if his disease is quiescent and the balance between the infection and the resistance was evenly maintained, have children if his wife was healthy? And still more so if the disease was arrested? He did not suppose there was much difference of opinion as to sanctioning the marriage and childbearing of a woman who had obtained and maintained an arrest of her disease for a number of years, or of opposing the marriage of a woman who was still actively tuberculous or who had only an apparent arrest. When the husband was actively tuberculous, but not in the advanced stage, and his wife was healthy it seemed to Dr. Otis that it was a question for him alone to decide whether he should have children; and if the child was at once removed from the father he did not believe the predisposition bugaboo need cause anxiety.

The Question of Rest and Exercise.—After the acute symptoms had subsided, for everybody agreed that abso-

lute rest should be maintained during the period of fever, when and how much exercise, if any, should be advised? Here opinions and practice varied. Dettweiler and Pratt seemed to have proved pretty conclusively that continued rest during the whole period of treatment produced excellent results. Could they show better results and fewer relapses from exercise, however graduated and supervised? E. Kuhn of Berlin had recently published a long and elaborate argument in favor of breathing exercise by means of his "lungensaugmaske" and adduced much theoretical and experimental evidence of its value. He considered that autoinoculation was produced not by general bodily exercise, as held by Wright and Paterson, but by the increased lung movement induced by bodily movements, and hence his conclusion that breathing gymnastics was the essential element in the production of autoinoculation. Upon how definite a scientific basis Paterson's theory of autoinoculation stood seemed still to be somewhat uncertain. At all events it was well to remember that continued rest had produced and did produce excellent results, and exercise at any stage of the game had its dangers.

He said it would seem to be rank heresy even to suggest that we had been overlooking, or applying without proper discrimination, the open air exposure in the treatment of tuberculosis, but did we always sufficiently individualize our patients in the application of extreme open air methods? He referred more particularly to the more northern latitudes. Even the far advanced incurable cases had frequently been subjected to this treatment; what was gained by doing this and rendering their last days more wretched? The earlier and so-called curable cases, but not all of them, were suitable for the rigorous outdoor system in the northern climate. Some, however, never became accustomed to the life and suffered genuine distress under the constant exposure to the cold.

The Question of Rest or Exercise in the Treatment of Pulmonary Tuberculosis.—Dr. Charles L. Minor of Asheville, N. C., spoke of the constant swing of the pendulum; a point between the two extremes of rest and exercise was the best to be had. The abuse of exercise was bad as well as the abuse of rest. In handling these cases of tuberculosis the management of rest and exercise was the chief thing. The word "exercise" was an elastic term. There should always be considered not alone the physical but the mental exercise. There were certain advantages of exercise in that it created an appetite, maintained the patient's strength and vigor, had its psychical effect, transferred food to muscle, prepared the patient for future work and beneficially effected metabolism. It was a difficult thing to judge exactly what amount of exercise should be allowed these patients. It was important that we should gain the confidence of our patients if we wished to obtain efficient results. It should be borne in mind that the reading of an exciting novel would run up the temperature, and even letter writing should be carefully guarded. Music, because it stirred the soul, was a bad thing, and so was hard study. One of the most troublesome things Dr. Minor had to contend with was the family, and he advised especially to keep the mothers away. He believed that exercises were rather underdone than overdone. Exercise created appetite and this was very important in that it kept up the patients' strength and vigor. The psychical effect was enormous. He always advised a two hours' rest, absolute rest, without reading, after the mid-day meal and without entertaining friends. He advised, however, against pushing the rest point too far.

Dr. Thomas Darlington of New York City said that it seemed to him that the two papers called special attention to one thing, and that was individual care, and that each case should be studied by itself and no set and fast rules laid down. "One man's meat was another man's poison," according to Shakespeare's dictum.

Dr. Charles L. Minor of Asheville, N. C., said that too much emphasis had been laid upon the harmfulness of marriage; we were all too strict on that subject. The effect of hope deferred was the worst thing possible for these patients. They should consider more the man, the woman, the child, and the community.

Dr. De Lancey Rochester of Buffalo, N. Y., said that if we allowed the tuberculous people to marry they should be instructed as to the seriousness of their condition. He believed that tuberculous women should not marry and bear children. He agreed with Dr. Otis in what he stated about the undue emphasis placed upon the physical signs in the early-diagnosis propaganda and that the character of the pulse should be studied as well as its frequency. In many of these cases there was an absence of cough and this should be studied in tuberculosis.

Dr. Charles Fox Gardiner of Colorado Springs referred to children of tuberculous parents who were not tuberculous; whether it was because of the climate or the care they got he did not know.

Dr. James Alexander Miller of New York City believed that Dr. Otis was right in what he had stated about the undue emphasis placed upon the physical signs in the early-diagnosis propaganda, and especially in New York City. It was his experience that there were thousands of cases investigated and reported to be tuberculosis—a diagnosis which was unwarranted from any clinical point of view. In many cases there would be found a slight variation from the normal without any physical signs of tuberculosis. Less than 20 per cent. of the patients in the clinics of New York had tubercle bacilli in the sputum. What Dr. Minor had stated about rest and exercise was true in every respect.

Saturday, June 20—Second Day.

Dry-Air Baths in Treating Tuberculosis.—Dr. Charles Fox Gardiner of Colorado Springs briefly outlined some of the more important recent advances that had been made in physiological medicine bearing on the subject and then he considered the practical side of air therapy as applied to the surface of the body in tuberculosis. The whole aspect of ventilation as affecting the human body, both by respiration and the skin, had assumed a new aspect, and they were now assured that the old idea of vitiated air poisoning the body by being rebreathed, as in respiration, was only partly true; the really poisonous effect of bad air was not due to rebreathing such air but to the blanket of stagnant, warm moist air surrounding the skin. The problem, therefore, was not a chemical but a purely physical one. This had been demonstrated by the simple experiment of agitating foul air by the use of electric fans when the symptoms of illness and distress, induced in people confined to such foul air, disappeared when the air was agitated, although no fresh air had been introduced to relieve them. Dr. Gardiner told of a method he had tried which consisted of an apparatus that, as nearly as possible, represented conditions found in nature when the open air bath was taken. The constant current of changing air found outdoors was artificially produced by an electric fan introducing a current of air that was first passed through screens. Those broke up the current of air, making it flow gently and avoiding any draft. The air at the intake was the room air at 70 degrees; it was not necessary to use cold, outdoor air, moving air being sufficient. This air, after its force was properly broken by screens, passed into a framework covered with the bedclothes, and placed over the nude patient, who remained in bed undisturbed, with the head uncovered and not within the framework. Inside this framework six incandescent lamps gave their heat to the skin and heated the body very much as did the sunshine in the open air bath. The advantages of this device were that it supplied some of the stimulus found in the open air baths, that the temperature and force of the air could be regulated at will, which was difficult out of doors, that by the use of the lights and the moving air humidity was brought to a low point, and, in short, an artificial climate could be created for the surface of the body that could be used in damp and cloudy weather when outdoor exposure was impossible; in pleasant weather the nude sun baths could be used if desired. One advantage was that those very ill were not moved from their position in the bed and by gradually cooling the air in the framework by turning off in succession one lamp after another, a safe and efficient method of reducing temperature without any depressing reaction was obtained. These results had followed his use of the air bath in treating tuberculosis. The skin humidity had been reduced at once from 22 degrees to zero and the general tonic effect had clearly followed that found in the open air cure now so common, without the unpleasant and sudden changes due to overcast sunshine, wind, and dust so often found outdoors. In conclusion Dr. Gardiner said that the warm, moist, stagnant air held by the clothes and coverings in contact with the body of a tuberculous patient was not agitated enough, even during the open air cure. This air, physiologically con-

sidered, was even of more importance to health than the fresh air inhaled. A method by which this surface air in contact with the body could be rapidly changed without danger of discomfort to the patient would prove of much value and should be used as part of the open air cure in selected cases.

Some of the Problems of Private Sanatoria for Tuberculosis.—Dr. FRANCIS M. POTTENGER of Monrovia, Cal., read this paper. His institution had just completed its tenth year and during this time there had been 1521 patients treated. There were two methods of running an institution. One was by military discipline and the other by considering the entire community as a family and expecting mutual regard and support. There were certain rules that must be lived up to rigidly; but in a private institution most of the rules must be somewhat elastic. The patient must be taken as an individual with an individual mind and individual temperament; and it was the province of those in authority to work with that mind and temperament and mold it into obedience. Personally he preferred the family spirit. The importance of early treatment could not be better emphasized than by the results which they had obtained in the past ten years. During the first stage, apparently cured and arrested, 97 per cent.; improved 3 per cent. During the second stage, apparently cured and arrested, 81 per cent.; improved, 14 per cent.; unimproved or died, 5 per cent. During the third stage, apparently cured and arrested, 38 per cent.; improved, 40 per cent.; unimproved or died, 22 per cent. In his short paper Dr. Pottenger took up some of the important questions bearing upon the sanatorium treatment of tuberculosis which were usually omitted from discussion, and he endeavored to show the relationship which the private sanatorium bore to the public on the one hand, and the members of the medical profession on the other. He also attempted to show the true relationship which should exist between the patient body and the medical staff and other attendants, thus pointing out the true place of the private sanatorium in the warfare against tuberculosis.

The Pottery Industry and Its Relation to Tuberculosis.—Dr. H. R. M. LANDIS of Philadelphia read this paper. He said that there was a growing interest in regard to the effect which occupation might have on the health of the working people; this was evidenced by the numerous laws relating to industrial hygiene which had been introduced yearly in the various State legislatures. If, however, they accepted the successful crusades which had been waged against lead and phosphorus poisoning, most of the remedial legislation had been directed towards the minimizing of accidents and very little had been done towards correcting evils which had a remote rather than an immediate evil effect on the health of the worker. The total number of people employed in the pottery industry in this country was about 16,000, and approximately 5,000 of this number lived in Trenton, N. J. Dr. Landis said that his own observations had led him to believe that more care should be exercised on the part of the workman in the disposal of the fragments of clay which were thrown off in the fashioning of the various utensils. Too much of it was allowed to fall on the floor about the work bench, and as a result was walked upon and quickly pulverized into dust. Face masks had been repeatedly advocated, but had never been particularly successful for the reason that the workmen were averse to using them. He believed that these individuals, especially those working in the dusty departments, should be subjected to frequent medical inspections. A compulsory examination three or four times a year would undoubtedly result in detecting many cases which otherwise would pass into the terminal stages of potter's asthma or tuberculosis.

Spontaneous Pneumothorax.—Dr. LOUIS HAMMAN of Baltimore, Md., made a report of a number of cases of pneumothorax coming on in otherwise healthy individuals and in one case recurring once on the opposite side and once on the same side. The absence of the usual symptoms of pneumothorax and the character of the physical signs were commented upon and he expressed the belief that the condition was frequently overlooked.

Lantern Slide Exhibitions.—Dr. THOMAS DARLINGTON of New York City gave a lantern slide exhibition depicting certain industrial conditions in which he had been specially interested during the past four years or more.

Heliotherapy in the Treatment of Bone and Joint Tuberculosis.—Dr. JOHN WINTERS BRANNAN of New York City likewise gave a lantern slide exhibition showing conditions as they existed at Sea Breeze Hospital on Staten Island, New York.

Blood-Pressure Studies, with Special Reference to the "Energy Index" and the "Cardiac Load."—Dr. GEORGE W. NORRIS and Dr. J. K. DAVIES of Philadelphia, Pa., presented this paper, which was based upon clinical blood-pressure studies undertaken with a view of determining the possibility of estimating cardiac efficiency by means of the two above-mentioned indices. The energy index, suggested by Barach, was established by multiplying the combined systolic and diastolic pressure by the pulse rate per minute. The cardiac load, suggested by W. J. Stone, was estimated by dividing the diastolic into the pulse pressure.

Angina Pectoris.—Dr. DE LANCEY ROCHESTER of Buffalo, N. Y., said that angina pectoris was a syndrome connected with many different states and the one condition present with all attacks was the interference with the function of contractility of the myocardium. He discussed the nature of the attacks and the treatment deduced from morbid conditions present. There was no standard of blood-pressure; what was high for one individual was low for another. The treatment must be of the individual and not of the symptoms. The general management of the case was very important in order to prevent recurrence of attacks.

The Comparative Value of the von Pirquet and Subcutaneous Tuberculin Test.—Dr. HUGH M. KINGHORN of Saranac Lake, N. Y., described the subcutaneous tuberculin reaction and gave the technique of giving it. He also told of the indications and contraindications for the test and the amount of fever necessary to constitute a reaction. He also described von Pirquet's tuberculin test and gave comparative results obtained in man with the subcutaneous and von Pirquet's tests.

Advantages of State Control Over County Institutions for the Care of Consumptives.—Dr. H. LONGSTREET TAYLOR of St. Paul, Minn., spoke of these advantages which insured control. It kept the standard high and avoided poorhouse methods. It put experienced sanatorium superintendents in charge and insured frequent inspection by State authorities.

Report of Four Cases of What Appeared To Be Tuberculous Meningitis, Followed by Apparent Arrest.—Dr. CHARLES C. BROWNING of Los Angeles, Cal., made this report and gave a lantern slide demonstration of one of the cases.

Differential Diagnosis of Mild Thyroid Toxemia and Incipient Pulmonary Tuberculosis.—Dr. C. G. JENNINGS of Detroit, Mich., read this paper. He said that mild thyroid toxemia might closely simulate incipient pulmonary tuberculosis. The symptoms common to both were the mild chronic pyrexia, the tachycardia, the debility, the shortness of breath, the indigestion, and the cough. The differential diagnosis would be made by the study of the temperature curve, the peculiarities of the tachycardia, the nervous phenomena, the derangements of digestion and metabolism, the physical examination, and the x-ray laboratory findings.

Percussion of the Lungs.—Dr. N. K. WOOD of Boston considered this subject in two parts—first, an effort to standardize the degrees of dullness, and, second, the advantage of percussing dogs from base to apex over the opposite method. He offered the following conclusions: 1. Present methods of percussion were of little value, because, far from having any universal standard of dullness, there was not in most instances even an individual standard. 2. To a field in which there was no accurate standard, he brought some standard, to him one that was definite and easily acquired. 3. Normal resonance was F to F sharp below middle C; 1 line dullness, or impaired resonance, was A below middle C to middle C; 2 line dullness, or definite dullness, was E flat to F above middle C; 3 line dullness, or very marked dullness, was B flat below intermediate C to intermediate C; 4 line dullness, or flatness, was E to F above intermediate C. 4. No intelligent idea of diagnosis, prognosis, nor of the underlying pathological condition could be formed by percussion without some such definite standard. 5. This standard could be acquired readily by the ear, and by the muscle sense of both hands, measured by the force of the plexor blow, and the resistance under the pleximeter. 6. Upward percussion was an absolute essential of correct work. The old method of downward percussion should be discarded, and no longer taught to medical students.

The Origin and Development of Auscultation and Percussion.—Dr. RICHARD C. NEWTON of Montclair,

N. J., gave a short sketch of the careers and discoveries of Auenbrugger and Laennec and made some observations upon the influence they exerted upon the medical practice of their time and told of the effects of these monumental innovations upon the history of medicine.

Election of Officers.—*President*, Dr. Henry Sewall, of Denver, Col.; *First Vice-President*, Dr. Arthur K. Stone, of Boston, Mass.; *Second Vice-President*, Dr. James Alexander Miller, of New York, N. Y.; *Secretary and Treasurer*, Dr. Guy Hinsdale, of Hot Springs, Va. The next place of meeting will be San Francisco, Cal.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 6, 1914.

DR. C. A. MCWILLIAMS IN THE CHAIR.

Appendicitis, General Peritonitis, Postoperative Paralytic Ileus, Enterostomy.—Dr. HERMANN FISCHER presented this patient, a man 52 years of age, who came to the German Hospital on September 19, after having been sick three or four days with acute appendicitis. He was operated upon the same day and a completely gangrenous appendix removed. There was a general peritonitis at the time of the operation. On the second day after the operation there was some abdominal distention, vomiting, and a temperature of 102° F. A distended loop of intestine projected into the wound. As the patient was in very bad condition an enterostomy was done. There was considerable escape of gas, and after two hours the abdomen was soft and flaccid. The patient improved from day to day. They knew that they had a high loop of the jejunum because bile and pancreatin juice flowed out and on the fourth day an attempt was made to close the enterostomy. The wound stayed closed for five days when there was a small opening. Three weeks after the last operation was performed, the loop was resected and the abdomen closed. In somewhat similar cases Dr. Fischer said he had not succeeded so well. There must have been some portion of the abdomen still free from infection; where the entire tract from the jejunum down was infected one was not likely to be so successful.

Ileocecal Tuberculosis.—Dr. M. I. BLANK presented this patient, a young man, whom he had first seen in August, 1912. At that time the patient complained of symptoms of appendicitis and an operation was advised. This was refused and he did not return until five months later when the possibility of tuberculosis suggested itself. Dr. Blank exhibited the specimen removed which showed tuberculosis involving the cecum, part of the ileum, and the appendix. A fistula persisted for six months after the operation and was then closed.

Resection of Large Intestine for Malignancy.—Dr. M. I. BLANK presented this patient. He was one of three patients who had come into the hospital as emergency cases complaining of symptoms of intestinal obstruction. At the time of admission he had been sick for ten days. A large growth which was exhibited was successfully removed from the sigmoid; it was adherent to the posterior abdominal wall. An intestinal anastomosis was performed in December, 1912, and the patient made a good recovery, and was now working eighteen hours a day. A second patient was admitted to the hospital on July 24, 1913, who also gave a history of intestinal obstruction. The tumor mass was low down in the sigmoid and the incision was made in the right rectus muscle below the sigmoid. In the third patient the growth was removed from the hepatic flexure. An interesting point in these cases was that malignancy was not suspected, the patients being operated on for symptoms of intestinal obstruction.

Aneurysm of the Profunda Femoris Artery.—Dr. J. A. CORSCADEN presented this patient. He was 20 years of age and at the time of his admission to the hospital gave a history of pain in the upper right thigh for the past two months. The tumor appeared in the upper third and was more marked on the anterior and outer part of the thigh. The pain was relieved by limping and throwing the weight on the toes. The patient gave a history of having been shot through the thigh seven years before by a 32 caliber pistol; the bullet came out through the gluteal fissure near the median line. The patient had no personal or family history of syphilis. The mass was visible on the outside, and on palpation was found to consist of two parts, an outside hard part and an inner portion firm and hard. There was a systolic bruit heard over a wide area. The *x*-ray showed a shadow and the pulses on the polygraph were synchronous and of equal force and volume. This mass was hour-glass in shape and the outer portion measured 12 x 4 cm. It was somewhat like a myeloma. The microscope showed calcareous deposits, but it was apparently an aneurysm of the profunda femoris artery. It could be assumed that it had ruptured with the formation of a hematoma. Dr. Blank described the operation by which the aneurysm was removed and the arteries united and said that an *x*-ray taken six weeks afterward showed that a shadow still persisted. Ten months later another *x*-ray was taken and a broader shadow was seen. Some thought this shadow was a calcium deposit and others thought that the bullet had chipped off a piece of the femur. The patient had made a good recovery except for loss of function of the internal saphenous nerve.

A Case of Disseminated Carcinoma of the Breasts and Axillæ Treated by Radium.—Dr. SINCLAIR TOUSEY presented this patient, a man who had been referred to him by Dr. Beder. The right mammary gland and nipple had ulcerated away and there was another ulcer below that region. Both were adherent and covered with a red parchment-like epidermis and were surrounded by an indurated margin projecting one-half inch above the level of the skin. Glandular masses larger than a hickory nut but smaller than a hen's egg were present in both axillæ and were widely scattered over the front of the chest. On the right side of the chest the skin over many of these was red and they were evidently in a way to break down into ulcers. On the left side the nodules were smaller, white, and extended from the nipple in a cord-like mass up into the axilla. The disease had been of several years' duration; no operation even for the removal of a microscopical specimen had been permitted. There was no history of syphilis and two careful Wassermann examinations were negative. The clinical diagnosis had always been carcinoma, and if so it was evidently similar to the cases of epithelioma cicatricans, which were sometimes active for as long as eight years before causing death. This patient had lost strength and weight, the skin was adherent to the chest wall, and the use of the right arm was interfered with. The treatment was by contact applications of 20 mg. of radium of 2,000,000 activity in a sealed glass tube three tenths of a millimeter in thickness, enclosed in aluminum one-half millimeter thick, and in thin soft rubber. The treatments were first given three times a week for a month and after that once a week. At each treatment several individual nodules or parts of the nodular borders of the ulcers received an application equal to a total of fifteen minutes in each place. During the first month every growth on the right side had been treated in this way and also the floor of the ulcers, but the left side had not been treated. At the end of this time all the nodular masses on the right side were perfectly flat, the cicatrized ulcers were no longer adherent but could be raised and bent double. The arm could be raised to the greatest extent. The patient felt stronger and had gained five pounds in weight. The left side, untreated, showed marked improvement, strengthening the author's belief that the application of the *x*-ray and radium to cancer developed some antibody which was carried through the system, and in proper dosage produced benefit to cancer foci beyond the effective reach of the direct rays themselves. Treatment was begun on the left side and the subsequent course of the case had been one of steady progress.

Tuberculosis of the Ileum, Perforated Stenosing Ulcer, Resection, Ileocolostomy.—Dr. SEWARD ERDMAN presented this patient, a Greek woman, 26 years of age. A diagnosis of appendicular abscess had been made, but at operation a condition quite different was found. The patient had never been ill until two months before coming to the hospital. At that time she had had a gastrointestinal upset but had recovered from that and remained well until her present trouble. On admission her temperature was 101° F. and the leucocyte count 21,000. An incision of the outer third of the right rectus muscle revealed a pus cavity containing fecaloid pus. This pus collection was extraperitoneal. There was a small opening which when enlarged showed a protruding bowel with a hardened tumor attached to

the anterior abdominal wall. A resection was done and it was found that this left only one-half inch of the ileum so an ileocolostomy was performed. On examination the specimen removed proved to be tuberculous. There was no involvement of the glands or of the mesentery though the wound acted as though there were. There was a sinus which persisted for six months and was still incompletely healed, a granular area remaining. An interesting point in connection with the case was that Greeks and Italians seemed to be more frequently the victims of intestinal tuberculosis than other nationalities.

Progressive Gangrene of the Foot, Due to Arteritis Obliterans, Cured by Arteriovenous Anastomosis.—Dr WILLY MEYER presented this patient, a man 29 years of age, who had come under his care in March, 1913. He was married, had children, and no signs of specific disease. He complained of pain in the lower right extremity and exhibited all the signs of endarteritis. Every remedy used for this condition had been tried without avail. The question was one of amputation, arteriovenous anastomosis, or, what Dr. Meyer said he personally considered much less desirable, double ligation and resection of the femoral vein. The patient entered the hospital on May 20, and an arteriovenous anastomosis of the femoral vessels was done in Scarpia's triangle. Dr. Meyer emphasized the point that in doing the anastomosis it was very necessary to be careful in ligating lateral branches and one should never use catgut but very fine silk for this purpose. The operative field had included an exposure of from three to four inches of the vessels. He did a typical end-to-end anastomosis according to the method of Carrel. An interesting feature in this anastomosis was the marked difference in the caliber of the vein and the artery after anastomosis had been accomplished, the former vessel being the larger one. Previous to the operation there was no pulse in the tibial or the popliteal artery. As the patient had intense pains from the gangrene of the large toe and the metatarsal portion the toe was amputated on the ninth day after the first operation. They all were pleased to find distinct arterial hemorrhage. There was arterial bleeding from the veins. The wound was closed by secondary sutures and healed very slowly. The man was now back at work without pain, gaining weight and Dr. Meyer felt that so far the extremity had been saved by the operation of arteriovenous anastomosis.

Dr. Meyer referred to the work and conclusions of several German authorities who did not think that this operation was of very much value. Dr. Meyer said that, in his opinion, theorizing was of like importance. It was the practical results that proved the utility of a procedure. He referred to a patient of Bernheim's, of Johns Hopkins Hospital, in whom arteriovenous anastomosis was done in all four extremities and all four were saved. The operation was certainly successful in a certain number of cases.

Progressive Gangrene of the Toes, Due to Trophoneurosis, Cured by Repeated Hypodermoclysis with Ringer's Solution.—Dr. WILLY MEYER presented this case. The patient was a young man of 28, who had another form of gangrene. There was no endarteritis as pulse in interior and posterior tibiæ was strong, there was no diabetes, no syphilis. The trouble was evidently due to trophoneurosis. Dr. Geo. W. Jacoby diagnosed syringomyelia of the cervico-dorsal segment. An older brother had had the same trouble and died after various amputations of both lower extremities in another hospital. This prompted Dr. Meyer to be conservative. This summer he had read that J. Koga of Ito's clinic in Kyoto, Japan, had treated thirteen cases of endarteritis occurring in individuals between the ages of 24 and 48 years of age by hypodermoclysis of saline and then of Ringer's solution with successful results in all the cases. The pain had stopped and the condition of the patients had improved. While arteriovenous anastomosis was a most fascinating field of operative endeavor it was a major operation and should not be resorted to until other measures had been given a reasonable trial. The present case was not one in which there was endarteritis. In endarteritis Ringer's solution was indicated. This patient had trophoneurotic gangrene of the toes, was anemic and reduced in every respect. In view of the sad experience of the patient's brother. Dr. Meyer decided to proceed cautiously. In general anesthesia the hypersensitive ulcers were thoroughly burned with Paquelin's cautery and later the effect of hypodermoclysis with saline or Ringer's solution tested. He first administered saline solution of four to five hundred c.c. every other day. After giving several injections of saline solution he gave Ringer's solution and the patient liked this better, finding it much less painful. After the patient had had about fifteen injections of saline and Ringer's, to his surprise, two of the eschars on the toes came off and underneath were strong, healthy granulations. The pain which had been intense for months ceased and the patient slept well and the wounds healed. He was now back to work and the foot was of comparatively good color, though at times part of it was blue. Dr. Meyer called the attention to the theory of Koga that the juvenile grangrenes were due to increased viscosity of the blood, that repeated hypodermoclysis thinned the blood or disposed of the elements in the blood that caused increased viscosity, thus improving the blood itself. If this theory was correct the results might not be permanent as the viscosity of the blood would not remain permanently altered in all probability. But then the simple treatment could be repeated.

A third case was presented. A young man, who had come under Dr. Meyer's observation with an obstinate ulcer of the foot at the German Hospital nine years ago and had been successfully treated by the transplantation of skin grafts. There was now endarteritis in both upper and lower extremities, pulses were absent and pain was constant and intense. He had been treated lately with Ringer's solution and was very much improved.

Cases of Muscle and Ligament Affections.—Dr. W. P. HERRICK presented a number of patients showing the beneficial effects of massage and movements in muscle and ligament affection. The first patient had ruptured the muscle fibers of the trapezius and had been cured by massage. A second patient who could scarcely raise the left arm had been greatly improved by two treatments. A third patient had sustained a strain of the foot and could not use that member, but had been cured by strapping and massage. Another patient was that of a boy with both cerebral and cerebella paraplegia. He had been unable to go upstairs and his muscles were entirely undeveloped; he was now apparently all right and his muscles in fairly good condition. Other patients who had suffered from flat foot, drop foot, disturbed innervation, and anterior poliomyelitis who had been helped by these methods of treatment were also presented.

Dr. SINCLAIR TOUSEY said that a question had been put to him as to whether after the disappearance of the nodules others sprang up. He had seen no new nodules appear and the patient said that none had appeared.

Dr. WILLIAM C. LUSK said that in regard to Dr. Meyer's case in which he had performed aretriovenous anastomosis, Leo Buerger had called attention to the fact that the veins as well as the arteries were obliterated. His experience in examining amputated extremities was that in six out of 19 that he had examined the venous circulation would have been inadequate to supply the limb.

Dr. CHARLES GOODMAN said he had tried the method of reducing the viscosity of the blood by infusions of physiological saline solutions in three cases with only temporary relief of the symptoms. Arteriovenous anastomosis had given varying results in different series of cases. Bernheim had collected fifteen successes out of fifty-two operations operated by thirty-two different surgeons. It had been suggested that the large number of failures could be accounted for by the lateness with which the patients had come to operation and because blood-vessel surgery was still in its infancy. Personally he had done fifteen operations with varying degrees of success. He had also performed a long series of experiments which controverted the arguments against arteriovenous anastomosis. That the reversal of the circulation was possible had been proven by Carrel. It had been demonstrated to take place in a dog in three hours. The fact of the reversal of the circulation had been proved by many other observers. A foot previously cadaverous took on warmth, and the pulsation of the veins could be demonstrated below the anastomosis. The valves of the veins offered only a temporary barrier to the passage of the blood; the one nearest the anastomosis gave away first and then the succeeding ones could be observed to follow. The etiology of the condition was obscure and until this was better understood we could not be sure of our therapy. the life of the limb. They had tried many varieties of In the laboratory of Beth Israel Hospital experiments were now being carried on which it was hoped would throw some light on this subject. It was sure, how-

ever, that in some instances this operation prolonged anastomoses but had found that the end-to-end anastomosis was the simplest and the least likely to be followed by thrombosis. As to whether Dr. Meyer's case was cured, Dr. Goodman said he did not think that one could say positively that a cure had been effected; they would have to know more about the etiology before they could make such a statement. He had studied a few cases for years, some for ten or twelve, and it had been his observation that the process was an ascending one and that later the veins became involved, neither did the disease limit itself to a single vessel, but parts of a number of vessels, both arteries and veins, might become affected.

Dr. J. A. Corscarden said that the veins were likely to be as much involved as the arteries, and the involvement was not necessarily continuous in either the veins or the arteries. Before operating one might determine whether the veins or arteries were at fault by constriction bands.

Dr. H. F. Wolf said that he thought the condition depended three-quarters on the red blood corpuscles and not on the viscosity of the blood, for after a time the viscosity of the blood became the same as before it had been altered by the Ringer's solution. Some cases were improved by baking, but the toes must not be included in the baking. Some cases had been improved by a new method of diathermy. In treating these cases with diathermy one should not use the high frequency current so popular in this country, but a low voltage and a high amperage, when the danger of burning would be lessened. He cited one case which had improved rapidly under this treatment.

Dr. Charles R. L. Putnam said he wished to add a favorable case in which a midtarsal amputation had been done for angioneurotic edema. There was gangrene of the stump and they did an arteriovenous anastomosis by the Bernheim method. As soon as the blood went through the veins the breaking down of the valves could be seen as had been described. The patient was still well though the edema had gone down to the ankle.

Dr. Willy Meyer, closing the discussion, said that the Wassermann test had been negative and that he had an end-to-end anastomosis. There were very few cases which would have been successful and he had feared that the operation would not do much good in this instance, but he attempted it on account of the youth of the patient. In one case in their wards there was total gangrene of the foot and he advised amputation only to find that the other extremity had been amputated at the thigh. Although this man was in much pain he still hoped that the leg might be saved by the hypodermoclysis. There was no other method that offered the hope of such a result. This much could be said: one could use the hypodermoclysis method for a few weeks; if this failed then arteriovenous anastomosis, and if this was not successful one could then amputate.

Ileocecal Tuberculosis.—Dr. Joseph Wiener presented this paper. He stated that our knowledge of this subject dated from 1891, in which year Billroth in Vienna, and Hartmann and Pilliet in Paris, simultaneously insisted on the fact that tubercular lesions existed in the cecum, lesions which before that time had been taken for carcinoma. Since then they had found that the cecum was more frequently the seat of tuberculosis than any other part of the alimentary canal. Both sexes were equally affected. It was found oftenest between the ages of twenty and forty years. Clinically there were two sets of symptoms, first those of peritoneal reaction, and secondly, those of intestinal stricture. As the disease when left to itself was always fatal, operation was indicated in all cases. The writer said that thirteen years ago he had been fortunate enough to operate on a very complicated case, which finally turned out to be ileocecal tuberculosis. Since that time he had been on the lookout for these cases and had succeeded in recognizing about ten others at operation. Cases of simple tubercular ulcers in the appendix were not included in this paper. These cases were often mistaken for appendicitis with inflammatory exudates. Most of their cases were operated on at the Mount Sinai Hospital since 1906. Many, perhaps most of these cases, came to operation with the diagnosis of appendicitis. In some of these cases there was a tubercular ulcer inside of the appendix or cecum, with an inflammatory exudate around the intestine. If some or all of this exudate were removed the pathologist was right in calling it inflammatory, but if one asked for serial sections through the appendix or cecum then often a small tubercular ulcer would be found which would clear up the diagnosis. The first case which the writer encountered was one of this kind. At the first operation the greater part of a large inflammatory tumor around the cecum was removed, and on section was pronounced chronic inflammation. At a subsequent operation, more of the tumor and the greater part of the appendix were removed, and again pronounced chronic inflammation. At a third operation for the closure of a fecal fistula, the stump of the appendix was removed and again the report came back, chronic inflammation. A more careful examination showed a typical tubercular ulcer in the appendix. The most practical classification of these cases had been made by Hartmann who distinguished two classes: First, ulcerative enteroperitoneal tuberculosis of the cecum, and second, hypertrophic cecal tuberculosis, the so-called ileocecal tubercular tumor. In the first class one found either ulceration with perforation and abscess formation, in which case the disease was serious and hard to cure, especially as fecal fistula often developed; or one found ulceration with stenosis, and frequently adhesions to the adjoining viscera or to the parietal peritoneum. Class two was the chronic form to which Billroth, Czerny, Terrier, and Hartmann had called attention. These cases usually presented a palpable tumor often of considerable size. The neighboring lymph glands were usually enlarged. In discussing the etiology of ileocecal tuberculosis the essayist reviewed the opinions of various authorities and concluded that the lesion was usually primary. A tubercular ulcer in the appendix would not always give symptoms. In one hundred consecutive autopsies of cases that died of tuberculosis, Sonnenberg found two cases of tuberculosis of the appendix, which had given no symptoms. Preexisting ileocecal disease was a predisposing factor to the development of ileocecal tuberculosis. In discussing the pathology of this condition the writer said that in the enteroperitoneal tuberculosis of the cecum one first found tubercles in the mucous membrane surrounded by an inflammatory zone. These tubercles coalesced and formed a flat ulcer with undermined edges. If such ulcers healed they produced more or less stenosis. As the process progressed tubercles developed on the serosa, and through these the lymphatics became infected. As a result there was an adhesive peritonitis and the neighboring loops of small and large intestine became adherent to one another and to the parietal peritoneum, and thus a palpable tumor resulted. In this way the disease might be limited to the affected area. Sometimes the ulcer caused a perforation of the intestine and resulting abscess. Adhesions to the parietal peritoneum came only late in the disease. This free motility was an important sign in the differential diagnosis. In the enteroperitoneal form of the disease the symptoms were not characteristic. There was gradual increasing pain in the right iliac fossa lasting several months; later vomiting, nausea, and belching. At times there was a slight evening temperature, loss of weight, and sometimes diarrhea with blood and mucus. After a time the mass was felt and was usually hard and not sharply defined. The symptoms in ileocecal tubercular tumor were similar to those just described at first, but later there was a stricture of the gut and one found severe colic, and the usual picture of intestinal obstruction. It was difficult to differentiate the enteroperitoneal form from appendicitis, and in the early stages it was difficult to differentiate the hypertrophic form from the foregoing and from appendicitis. It had also to be differentiated from carcinoma. In carcinoma one did not find the symptoms of intestinal obstruction, certainly not early in the disease. The pain was not so severe, and the tumor was apt to be more fixed. In tuberculosis the tumor was apt to be smooth and in carcinoma nodular. In children one must also differentiate from ileocecal intussusception. The treatment consisted of artificial anus formation, complete intestinal exclusion, ileocolostomy, with or without intestinal exclusion, and partial or complete excision of cecum and ileum. The removal of the appendix was indicated in practically every case. Artificial anus formation was rarely indicated and then only as a temporary expedient in desperate cases. Complete intestinal exclusion was performed in a few of these cases, but it would rarely be indicated today. Ileocolostomy with or without intestinal exclusion was a simple operation with low mortality and would cure a large number of cases. They had been accustomed to do it by the same technique as was employed in doing a Moynihan gastroenterostomy, using clamps and linen sutures. If there was no ab-

scess after removing the appendix the abdomen was closed without drainage. The anastomosis should be made far enough away from the diseased area to allow of a subsequent resection of gut. This lateral anastomosis could be combined with intestinal exclusion. This would be indicated in cases involving a large part of the ileum and ascending colon, but in many cases the anastomosis alone would bring about a cure. As to the excision of the intestine, extensive adhesions around the diseased area formed a contraindication, on account of the great risk involved, to an immediate excision. If the tumor could not be lifted out of the abdomen the dangers of excision were too great. If the tumor was freely movable and an excision was to be done, after lifting the tumor out of the abdomen, the mesentery of the ileum and the mesocolon were ligated close to their intestinal attachments and divided. The ileum and cecum were clamped and the intestine cut away. Mikulicz did the resection in two stages. At the first operation the tumor was brought out of the abdomen and the abdominal wound was carefully sutured. At the second operation the intestine was resected. It seemed better to do a lateral anastomosis at the first operation, and then if necessary at a second sitting to do the resection. Proceeding along these lines many cases would be cured at the first operation, and with a low mortality rate; whereas the intestinal resection would always give a high mortality.

Dr. Samuel G. Gant expressed the opinion that ileocecal tuberculosis was not as rare as Dr. Wiener's paper would indicate. In fact the region was a favorite site for tuberculous foci, hypertrophic or neoplastic tuberculosis was a rare condition but was located in the ileocecal region more often than elsewhere. Owing to the absence of lung complications here some authorities considered hypertrophic tuberculosis of primary origin caused by bovine bacilli. Patients afflicted with hypertrophic tuberculosis did not have a typical tuberculous appearance and the swelling could be differentiated from carcinoma by its slow growth, smooth contour and elasticity, absence of cachexia, and by the fact that the patient had lost but little in weight. Intestinal exclusion alone or as a preliminary step to ileoccecal excision gave the best results.

Dr. Joseph Wiener said that a large majority of cases occurred in young adults under thirty years of age so that carcinoma would seem by this fact to be ruled out.

Massage and Movements for Certain Affections of Muscles and Ligaments.—Dr. W. P. Herrick presented this paper. Before entering on the discussion of his subject he warned his hearers that massage and movements were not a "cure-all," but valuable aids for certain conditions. The neglect of these measures gave a sound plank to the rotten ships of charlatanism and cults and in abandoning certain patients to these chance fates they were leaving undone some things which they ought to have done and were losing a meed of praise that was rightfully theirs. A visit to the clinics and hospitals of the city where this line of treatment was employed showed much good work; this was especially true of orthopedic and neurological institutions, but it was surprising that priority so limited massage to the treatment of fractures, old dislocations, etc., with a scattering of cellulitis, contractures, and the like, when massage was essentially adapted to muscular structures and accessible ligaments which offered a great field, as did some of the disturbances of the digestive tract, peripheral nerves, etc. Massage was mainly manual and should naturally interest surgeons, those who worked with their hands. Even a little practice gave delicacy and firmness of touch, with detection of indurations, or atrophies of muscles, or tender points of spinal exit, or peripheral distribution of nerves. The subject, however, was rarely taught in our colleges and this resulted in indifferent knowledge and interest and restricted the physiological application, tending to make it a last rather than an early resort. It was well known that muscle and ligament affections were often precursors of deformity and predeformity was a natural branch of prophylactic surgery whose growth should emulate prophylactic medicine. The importance of massage and movements for impaired nutrition or function of muscles and ligaments was the key-note of this paper.

The essayist pointed out how massage and movements aided impaired nutrition and function, hastened repair, and broke the vicious cycle of injury or disease. The writer stated that massage was contraindicated in acute infection, but was indicated in traumatism of ligaments and muscles, was an aid in restoring function and nutrition of muscles, and beneficial in disturbed innervation of muscles. In considering the traumatisms he spoke of contusions, ruptured muscle fibers, myosites, and sprains, and cited cases illustrating the benefit in these conditions of massage and movements. In myositis, which often followed a forgotten strain or injury, and was oftenest located in the lumbar, deltoid, or trapezius muscles, there was generally tenderness with loss of power, severe pain or attempted function, often indurated area, and these conditions responded well to massage. In the application of massage as affecting the nutrition and function of muscles Zabludowski found in man that after severe exercise a rest of fifteen minutes brought about no essential recovery, while after massage for the same period the exercise was more than doubled, showing prompter recovery from fatigue. Professor Maggiora of Turin also showed that muscles concerned in a special movement could do about twice as much work after a few minutes' massage, as without it. In this connection the essayist cited a case of cerebral and cerebellar diplegia which had been greatly improved by massage. Massage might aid relaxed muscles to regain their tone, especially when overstretching was prevented, and contractured muscles might to a limited degree be stretched. An anesthetic for breaking down adhesions or tenotomy for a contractured muscle might be preferable to massage or movements alone, but either was aided by subsequent manual treatment. Similarly relaxed ligaments through increased nourishment, especially with adjacent tendons aiding through development of their muscles, might regain normal function, and contratured ligaments be elongated. The common conditions of weak foot and flat foot well illustrated some of these conditions. In considering the effects of massage on innervation of muscles, the essayist urged the importance of early treatment in temporary conditions of impairment and emphasized the point that nerve centers were associated, and apparently in a nerve trunk fibers went from one center to several associated muscles and a muscle received fibers from several associated centers, so, though many cells might be destroyed, all nervous control of the muscle might not have been lost, but simply in abeyance or diminished. Thus it seemed possible that certain cells might vicariously take up functions of destroyed cells, while many believed that muscular function hastened completion of nervous control. The natural indications in this class of cases then were to early combat atrophy with nourishment, to encourage function and improve it by education, to nourish regenerating axis cylinders, and to avoid interference with function in obviating deformity, though a destroyed muscle might demand tendon transplantation.

The author also considered the effects of massage and movements on the muscles and ligaments in anteriorpoliomyelitis and said that these had been shown in hundreds of Lovett's cases and of Dr. Fraser's of Rockefeller Institute which would soon appear. In closing Dr. Herrick related the history of a case of poliomyelitis of ten years' standing as an indication of methods in late stages of the disease. In 1903, feeling that the brace severely interfered with function and nutrition, they determined to substitute massage and function endeavoring to foresee and obviate deformity by any other means possible. The case chosen was a little girl, five years of age, who had an anterior poliomyelitis of two years' standing. She had been treated with electricity and had worn a brace. Examination showed three-fourths of an inch shortening of the left leg, with atrophy of the leg and thigh. Drop foot was present so that the toe was dragged in walking with some inversion of the foot. The brace was removed, a laced raised shoe ordered, and massage and motion exercises instituted. The muscles developed up to those of the other limb, though it was a year or two before she was able to run normally. She was now taller and heavier than her mother, wore a thick sole on one side, but otherwise was entirely normal and indulged in normal exercise as running, dancing, ice-skating, etc. Subsequent cases had strengthened their belief in this method so that now after the acute stage they taught the mother to give the massage and it was given at the clinic three times a week. They found muscles recovering function years after the attack. Dr. Herrick also described the method of muscle strapping which they employed.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held May 26, 1914.

Dr. GEORGE W. KOSMAK IN THE CHAIR.

Report of a Case of Gangrene of the Lung Following Operation for Ectopic Gestation; Resection of Rib; Recovery.—Dr. LILLIAN K. FARRAR reported this case, which occurred in a woman thirty years of age. She had had no children, but one spontaneous miscarriage. She gave a history of vaginal discharge beginning immediately after her marriage nine years previously. Her present illness began in December, 1906, when, after a delayed menstrual period, she flowed profusely and had sharp cutting pains. She was sent to the speaker, in March, 1907, with the diagnosis of ectopic gestation. Pelvic examination revealed a cervix hard in consistency, a uterus slightly enlarged and displaced to the right, and the left tube palpable and moderately prolapsed. To the right of the uterus was a large mass indefinite in consistency, markedly pulsating, and moderately tender on palpation. A moderate amount of decidua was removed by curettage. On opening the abdomen the right tube was found enlarged at the distal end to the size of a goose's egg, deep dull red in color, and firm in consistency. A large number of old blood clots were adherent to the intestine. The right tube and ovary were resected, and the left tube and appendix removed. The patient was returned to the ward in good condition. That evening the speaker found the window open back of the patient's bed and a strong wind blowing on her. The following morning the patient's temperature rose, her pulse and respiration were accelerated, and she could not speak above a whisper. In a few days her sputum became copious, tenacious, and with a marked sickening odor. The abdominal condition progressed in an absolutely normal way. Ten days after operation the patient developed dullness and bronchial breathing over an area about the size of a silver dollar in the right lung, posterior and to the right of the angle of the scapula and in the fifth interspace. Twenty days after operation the sputum contained a moderate number of pneumococcus bacilli and elastic tissue. On April 14, twenty-two days after operation, the temperature became septic and the pulse and respiration more rapid. The patient was aspirated at the level of the sixth rib, but no fluid was obtained; she was then aspirated at the level of the sixth rib, one inch to the right of the angle of the scapula, and on finding fluid, greenish in color, two ribs were resected. The culture from the fluid obtained gave a pure culture of the pneumococcus bacilli in agar-agar and calcium broth. The lung was retraced and converted into a gray-green pulp. At its lower border was a cavity about an inch in diameter coated with a greenish white slough. The odor was intensely sickening. The patient made a slow recovery from this time. The points of interest in this case were: (1) The marked anemia of the patient following the prolonged flow of blood. (2) The exposure to cold when the vitality of the patient was lowered following operation. (3) The presence of blood clots adherent to the intestines. The primary union of the wound. (4) Aseptic embolism carried into the pulmonary artery. (5) The area of central Pneumonia without physical signs until the tenth day. (7) The presence of the pneumococcus not demonstrated until the twentieth day. (8) The septic temperature on the twenty-second day, and the purulent effusion on the twenty-seventh day.

Rupture of the Corpus Luteum with Free Intraperitoneal Hemorrhage.—Dr. MILTON R. BOOKMAN reported this case. This patient was admitted to the Lebanon Hospital February 29, 1912, with the history of having been suddenly seized with severe cramp-like pains in the abdomen two days before, followed by vomiting and retching. The pains became localized in the lower half of the abdomen. The only abnormality revealed by physical examination was some muscular resistance over the lower half of the abdomen, especially over the right side; this was not distinct rigidity, but more in the nature of a voluntary spasm. At operation performed on the day of her admission the peritoneum was found to be dark violet as in cases of ruptured extrauterine pregnancy. A considerable amount of fluid and dark clotted blood escaped at this time. The right ovary was found enlarged to the size of a small hen's egg, and there was considerable bleeding from a small hole near the hilum. As several sutures cut through the ovary, it was ablated, and the appendix, showing considerable congestion, was also removed. The patient made an uneventful recovery. The pathological report showed that there was some fibrous degeneration in the ruptured corpus luteum. The appendix showed some exudative inflammation and marked congestion of its peritoneal coat. The sequence of events in this case was undoubtedly a catarrhal appendicitis of a mild grade, and, with increasing abdominal pressure from the vomiting, there followed the rupture of the corpus luteum with the symptoms overshadowing those occasioned by the appendical inflammation. A few cases of intraperitoneal hemorrhage due to a rupture of a normal Graaffian follicle had been reported. Hadley had made a study of eighteen cases and concluded that there seemed to be no reason to doubt that the actual process of the formation of ovarian hematoma was one of rupture of several or many Graaffian follicles into one another, instead of on the surface of the ovary separately. The difference between the ovarian hematoma and the case in which the blood suffused the peritoneal cavity was simply one of degree; in the former the blood was extruded slowly from the tear in the ovary and had time to clot, while in the latter the blood was poured out into the free peritoneal cavity with the symptoms of intraperitoneal hemorrhage. The classification into the affections of the Graaffian follicle and those of the corpus luteum was also misleading, inasmuch as the Graaffian follicle was but the immediate precursor of the corpus luteum. In young girls cases were often seen in which they complained of severe pain at the menstrual period with a slight elevation of temperature and some nausea or vomiting; these cases were usually ascribed to "catching cold" or to an attendant catarrhal salpingitis where the condition was no doubt due to a small pelvic hemorrhage from a corpus luteum that had been ruptured. The so-called pelvic hematoma were no doubt caused by similar process with the subsequent encysting of the blood, and many of the adherent ovaries with normal tubes might be ascribed to a similar cause. Infection with the formation of corpus luteum abscesses was fairly frequent, and, according to Cohen, was usually due to the gonococci or tubercle bacilli, rarely to streptococci, staphylococci, or penumococci, the colon bacilli and the anaerobic organisms playing a minor part. The diagnosis was difficult. From a low appendicitis of a mild type it was very difficult to differentiate, although a high white cell count might help one. From a ruptured extrauterine pregnancy the condition might be differentiated by the absence of uterine bleeding and pressure, decidual fragments, and perhaps physical signs. From the literature it seemed that rupture of a corpus luteum had never been diagnosed. The treatment of the mild cases in which this condition might be suspected was mainly symptomatic. In the severe cases in which there was profuse bleeding, operative interference was indicated. The prognosis in all cases was good except where there was a coexisting hemophilia or leucemia.

Liver from Case of Eclampsia, Showing Extensive Subcapsular Hemorrhage.—Dr. GEORGE W. KOSMAK presented this report. The patient was an Italian, nineteen years of age, admitted to the Lying-In Hospital seventeen hours after delivery in a state of coma. Her pregnancy had been apparently normal until the previous day, when she was seized with convulsions, and was delivered the following morning at her home. She had twenty-one convulsions, went into coma, and died a little over thirty-six hours after her admission to the hospital. At autopsy the liver was found enlarged, weighing 2,470 grams, and presented numerous subcapsular hemorrhages scattered over its entire surface. Sections of the liver showed many hemorrhagic areas throughout the substance of the organ. Microscopical examination showed necrosis, autolysis, and disintegration of the hepatic cells of the central two-thirds of the liber lobule. There were also many hemorrhagic areas throughout the liver substance which had destroyed the hepatic cells from pressure. Many of the cells showed cloudy swelling, but there was only a very small amount of fatty degeneration present. The kidneys showed an acute diffuse nephritis, the spleen a few petechial hemorrhages, and the lung an edematous condition, many of the air vesicles being filled with blood.

A Case of Suppurative Appendicitis Occurring During Pregnancy.—Dr. WILHELMINA AFTON RAGLAND reported this case, which occurred in a patient twenty-eight years of age, in the third month of pregnancy.

She was admitted to the hospital complaining of severe cramp-like pain in the right lower abdominal quadrant, from which she had been suffering for a week. She appeared to be in fairly good condition except for attacks of pain lasting about a minute at intervals of one-half hour. Her past history was negative save for an attack of typhoid fever at the age of eight years, and of *ardor urinæ* at the age of eighteen, which had lasted but a few days. She had been treated for the past week for appendicitis by her family physician, who referred her to the hospital. The physical examination was negative except for an indefinite cystic mass in the right lower abdominal quadrant, extending from the symphysis pubis to about five cm. below the umbilicus. It seemed to be confined to the right side of the median line, but the abdominal walls were tense and rigid, and examination caused considerable pain. The tumor-like area seemed to be adherent to the uterus, and ovarian cyst and hydronephroma were also considered in the diagnosis. The condition of the patient did not change materially until the fourth day, when it was found that the abdomen was five cm. larger around the iliac spines than when the patient entered the hospital. The fifth day with the patient under an anesthetic the mass was palpated and operation was decided upon and proceeded with immediately. A large abscess was opened and the proximal end of the appendix was found leading into the sac. After operation the temperature rose to 103 F.; marked distention of the abscess and great distress followed and continued for six days. At the end of this time the fetus was spontaneously expelled. The placenta remained behind and was removed by the placental forceps. The temperature then subsided and the patient was comparatively comfortable for three days, when an indurated mass was palpated in the right fornix by vaginal examination. This gradually disappeared and the patient in time made an excellent recovery.

The interesting features of this case were: (1) The absence of any history of constipation, either before or during pregnancy. (2) This was apparently a primary attack of appendicitis. (3) The leucocyte count (14,000). (4) The late abortion, six days after operation, and two weeks after the onset of the attack. (5) The adherent placenta which was attached to the portion of the uterus which formed the abscess wall and thus led to the belief that the abortion was due to direct migration of the *B. coli communis* into the placenta. (6) The low grade of the sepsis. Three blood cultures which were made during the course of the illness were negative.

Constitutional States in Relation to Gynecological Conditions.—Dr. ROSALIE SLAUGHTER MORTON presented this communication in which she stated that the surgical treatment of gynecological conditions had in many instances been so brilliantly successful, and this, together with the general tendency to specialize, had caused a loss of interest in and a lack of attention to the relation of systemic states to gynecological conditions. As a result of the failure to recognize this relation between constitutional states and gynecological conditions many patients had received little benefit from the treatment given by gynecologists in certain cases. All the constitutional states in women might have a gynecological significance, and, broadly speaking, depended upon nutrition and elimination. They might be divided into disturbances of the circulatory, respiratory, nervous, digestive, and renal systems, improper formation or adjustment of the bony framework, and improper functioning of the ductless glands and the skin. A determination of the extent to which any or all of these affected the generative organs, or were affected by them was the most important sociological and gynecological consideration of our day. The essayist limited herself to a brief discussion of each of these nine heads mentioned. She called attention to the effects of postural deformities, such as round shoulders and incorrect standing, which might lead to anemia, malnutrition, pelvic neuralgia, and amenorrhea. Lordosis was apt to have a marked effect on the pelvic contents, allowing a sagging of the intestine. Interference with the circulation and misplaced pressure were very often responsible for the evil effects of both postural errors and lordosis.

The writer discussed the effects of pathological conditions of the gastrointestinal tract on the pelvic contents and emphasized the frequency with which lesions of the gall-bladder and appendix complicated or obscured the diagnosis of ovarian disturbance. Pelvic pressure due to colonic angulation at the hepatic flexure produced by gall-bladder adhesions caused dilatation and prolapse of the cecum, which not only led to acute congestion of the right ovary, but interfered with the emptying of the rectum to a degree which induced chronic constipation, toxemia, and neuritis, as well as uterine congestion. Dr. Morton had devised an abdominal speculum by means of which the entire abdominal cavity might be inspected through the small incision used in the average gynecological operations. The observer by turning the speculum could inspect without handling the cecum, ascending colon, stomach, splenic flexure, descending colon, sigmoid, and various portions of the ilium. Rheumatism and malaria were systemic conditions giving gynecological symptoms; the dysmenorrhea due to these yielded only to constitutional treatment. The essayist then discussed the manifold gynecological effects of alterations in the circulation and gave the results of a comparative study of blood pressure in men and women, showing that the rhythmical fall of blood pressure at definite intervals occurred in both men and women. The daily records of men and women gave curves which were indistinguishable in character. Loss of blood from hemorrhages of the genital organs might be productive of anemia and changes in the heart muscle and the circulation as well as in the blood picture. Anemia was a frequent cause of painful menstruation. Uterine prolapse, version, and flexion were so commonly associated with poor tissue tone in anemic girls and in those who in customary phrascology "outgrew their strength," that systematic outdoor exercise from little girlhood was a valuable preventive measure. Congenital smallness of the arterial system associated with narrow arch of the aorta might be associated with sexual infantilism. Severe primary anemias or pernicious leucemia led usually to amenorrhea. If the uterus was the seat of hemorrhage due to atony of the uterine muscle which encouraged a continuance of the bleeding, treatment of the anemia and improvement of the general health lessened the tendency to metrorrhagia more successfully than local treatment. If this failed hysterectomy might be necessary, as the speaker said that girls under twenty had been known to bleed to death as the result of uncontrollable menorrhagia and metrorrhagia.

Dr. Morton showed the importance of the consideration of the pathological conditions of the genitourinary system in its relation to the gynecological condition. Patients often sought the advice of a gynecologist for what Goodwin called the "intangible, imponderable, invisible pelvic pains of neurotic women," and in the opinion of the author these were frequently due to undiagnosed nephritis, which, though showing only a trace of albumin, might so lower the nerve tone of the patient that she had no resistance with which to meet the periodical physiological pelvic congestion which made no tax upon normal women. The essayist reviewed the relations of cystitis, pyelitis, and gonorrheal infection of the genital tract, and stated that the relation of the nervous system to gynecology had proved a profitable field for much valuable work and speculation. The essayist reviewed evidence showing that insanity had no marked influence on gynecological conditions and that such conditions were not more frequent among the insane than among others. Operative measures in the insane might result in improved physical condition without any alteration of the mental state. In a study of the effects of fatigue incident to modern industry Dr. Morton's figures indicated that the number of men who sought relief in three large department stores investigated was in about the same ratio as among the women. It seemed that the physically perfect woman had physical endurance equivalent to that of man and had no pelvic complications.

Instances might be cited showing that where women had sufficient outdoor exercise they stood the strain of mental work quite as well as men. The normal changes to and from the child-bearing period were almost imperceptible in a perfectly healthy girl and woman. Dr. Morton also considered the influence on the genital organs of non-toxic doses of poisons, the effects of opium, morphine, codein, heroin, and acute infectious diseases, and reviewed the theories in regard to the functions of the ductless glands, taking up successively the ovary, the mammary gland, the hypophysis, pituitary, pineal, suprarenals, thyroid, and parathyroids.

Therapeutic Hints.

The Treatment of Acute Bronchitis.—William Hanna Thomson notes that the indications for treatment in an attack of acute bronchitis are to promote the free flow of the secretions and to allay the spasm. The former indication is met by the use of oils. Of these linseed oil is the best. It is given as an emulsion prepared according to the following formula:

℞ Irish moss, 1 ounce.
Marshmallow root, 2 ounces.
Water, 3 pints.
Boil one-half hour; strain to 3 pints; add linseed oil (15 ounces) to make emulsion.
Oil of wintergreen, 2 drams.
Oil of cassia, 2 drams.
Glycerin, 5 ounces.
Simple syrup, 10 ounces.
Dilute hydrocyanic acid, 160 minims (1 minim to each tablespoonful.)

The dose of the above is one tablespoonful.

A second formula rontains the same ingredients with the addition of the following:

Chloral hydrate, 15 grains.
Magendie's solution, 5 minims to each ounce.

The author has rarely found an attack of acute bronchitis which is not relieved within forty-eight hours by the use of this remedy.—"Clinical Medicine."

The Treatment of Obesity.—J. Carles points out that in the treatment of obesity the various types of this condition must be borne in mind. Thus in its etiology the following factors play an important rôle: overfeeding, heredity, digestive disturbances, and anomalies of the internal secretions. Ovarian extract is of value in the obesity of the menopause or in that following ovariotomy, and testicular extract is of value in the obesity resulting from atrophy of the testicles. Thyroid administration is indicated in cases of obesity associated with a larval myxedema. But in this condition it is important to give only very small doses of the remedy, e.g., from 0.025 to 0.50 gram per day. There is an infectious or a toxic type of obesity whose etiological cause may be difficult to control. To this category belong the obesity following typhoid fever and that associated with syphilis or florid tuberculosis.—*Journal de Médecine de Bordeaux.*

An Empirical Remedy for Asthma.—C. Leclerc states that the magicians of Anam and Tonkin have for a long time employed in the treatment of asthma a substance obtained from the salivary secretion of sperm-whales. The natives collect this secretion whenever one of these animals is caught. This secretion when dried is of a sticky and elastic consistency, of a grayish color, and of a slightly bitter taste. It is employed in doses of 1 or 2 grams per day. The remedy is called "long-duyen-huong." It quickly relieves an attack of asthmatic dyspnea. It causes no gastric derangement but gives rise to a metallic taste which is similar to that produced by potassium iodide. The fact also that it lowers arterial pressure like potassium iodide leads the author to believe that "long-duyen-huong" owes its antispasmodic property in all probability to the presence of potassium iodide in organic combination.—*Gazette des Hôpitaux.*

SERUM TREATMENT OF PNEUMONIA.

BY JOSEPH C. ROPER, M.D.

NEW YORK.

FROM THE FIRST MEDICAL DIVISION OF NEW YORK HOSPITAL.

AT New York Hospital in February, 1909, an attempt was made to produce a potent immune serum for the treatment of cases of lobar pneumonia. The method employed in immunizing the horse was based on theoretical possibilities suggested by a series of experiments performed on rabbits. In these experiments, however, other antigens than those of the pneumococcus had been used.

In the preparation of our animal a vaccine was used which contained 5 strains of pneumococci, including typical and atypical types. These organisms were killed at various temperatures and injected subcutaneously in increasing doses at three-day intervals. The general condition of the horse seemed to be but little affected by the injection of the antigen until toward the end of the period when the animal lost weight and showed other evidences of poor condition.

After six weeks of vaccination the use of the serum was undertaken whenever a frank uncomplicated case of pneumonia presented itself. During the time the serum was being withdrawn for use the injections were continued. Bleeding, however, was never done until at least twenty-four hours after an injection. Having in mind the possibility that even after twenty-four hours the serum might contain uncombined antigens as well as antibodies, it was deemed unwise to begin with large

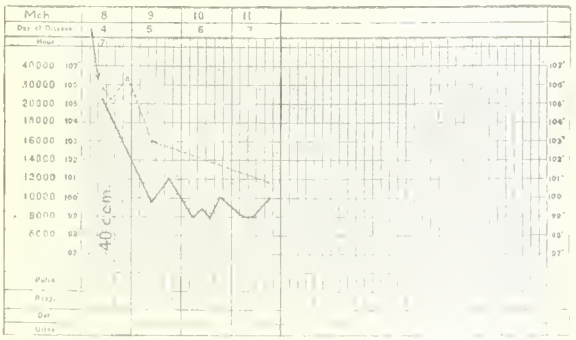

CHART 1.—Dotted lines show leucocyte levels. Arrows indicate points at which serum was given. Figures indicate amounts of serum in centimeters.

doses. The first cases treated therefore received very small doses, given subcutaneously. These having been followed by no noticeable immediate improvement or bad effects, larger doses were given and the intravenous method was adopted.

The results for a time were encouraging as far as the mortality was concerned. Thirteen of the first fourteen patients treated recovered. There

seemed to be an improvement in the general condition of these patients following the injection of the serum, but the temperature curve showed no material change, and there was no shortening of the course of the disease. In all twenty cases were treated. As remarked above, all but one of the first fourteen recovered. Of the six, toward the end of the series three died, and the total mortality was 20 per cent., approaching but somewhat lower than the average hospital mortality for this disease.

While at that time it seemed possible that failure in the later cases of the series might be due to the change in the health of the horse producing the serum, the results on the whole did not seem to warrant the conclusion that an active serum had been produced. In going over the records after five years this conclusion seems justified. No clear-cut results were obtained, and the work was temporarily given up. It will be remarked that the doses administered were very small when compared with those considered adequate at the present time. Neufeld, calculating from protection experiments on animals, has concluded that at least 75 c.c. of an active serum should be administered to an adult.

Table I gives a record of this series.

In January, 1913, a second attempt was made to produce an efficient serum. The horse in this instance was treated with increasing doses of a vaccine prepared as before. Five strains of pneumococci were used (including Neufeld I). A *Streptococcus mucosus* isolated from one of our cases was added at a later time. Daily intravenous injections of the vaccine were given.

After two months' treatment serum was withdrawn as required, the daily vaccination being continued but twenty-four hours always intervening between vaccination and bleeding. Only frank

*Read at the 263d Regular Meeting of the Practitioners' Society, May 1, 1914.

cases were treated, and to avoid coincidence as far as possible an attempt was made to confine the work to relatively early cases. The number of these is not large, as very few pneumonia patients enter the wards of a general hospital before the fourth day of disease. The only cases in this series with a history of three days since onset were alcoholics. These patients are often hazy concerning their early symptoms.

TABLE I. SERIES OF 1909

The serum was given intravenously to all the cases of this series, and doses were used which approximated those advised at the present time. Three patients were treated with the first lot of serum. Two of these defervesced immediately (Charts 1 and 2), but the third, while going on to eventual recovery, showed no immediate effect. No defervescence occurred in the other cases treated, but some of the patients developed phenomena almost as striking. Four had chills following within two hours after the administration of the serum. In one the temperature went to 108 and in a few hours dropped to 98 (Chart No. 3). Two had temperature of 106° following their chills and a drop shortly afterward to 99° (Charts Nos. 4 and 5). The fourth showed much less disturbance (Chart No. 6). The temperature of all four returning to a high level in a short time, and the course of the disease was unaffected. Some of the remaining cases showed an apparent improvement in their general condition, while others were entirely unaffected.

Leucocyte counts were made in all these cases before giving the serum and two, four, and six hours after giving, but no effect could be found which might be attributed to the serum.

Blood cultures were made in all the cases, but were positive in only two. Excluding the case due to the *Streptococcus mucosus*, two patients died of twelve treated, a mortality of about 17 per cent.

Table II gives a record of this series.

It will be noticed that no attempt was made in this work to differentiate the type of pneumococcus involved. A polyvalent vaccine was used, and the serum should have been a polyvalent serum, and if active it was expected that it would give enough definite results to warrant going into the work in greater detail.

Pneumonias may be divided into those due to typical and atypical organisms, the former being common and the latter uncommon. A polyvalent serum active against the typical varieties should show results in the great majority of cases.

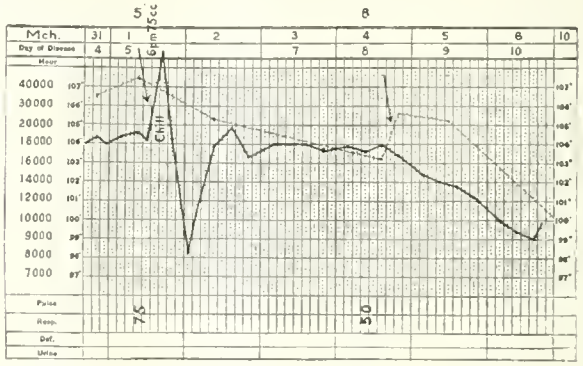

CHART 3.—Dotted lines show leucocyte levels. Arrows indicate points at which serum was given. Figures indicate amounts of serum in centimeters.

Roemer has produced polyvalent sera which Neufeld found protected animals against the typical varieties of pneumococci. Using a polyvalent serum prepared as advised by Neufeld and Haendel,

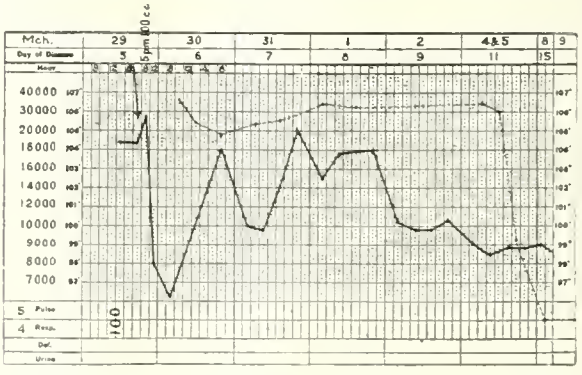

CHART 4.—Dotted lines show leucocyte levels. Arrows indicate points at which serum was given. Figures indicate amounts of serum in centimeters.

Weitz has treated thirty-seven cases. He injected 10 to 40 c.c. intravenously, some patients receiving one dose and others two or more at one-half, one or two-day intervals. Of sixteen cases treated on second day, two were normal on third day; ten

were normal on fourth day; 1 was normal on fifth day; three were unaffected (one died). Of fourteen cases treated on third or fourth day, nine were normal after two days, two showed no change, and three died. Of seven cases treated on fifth or

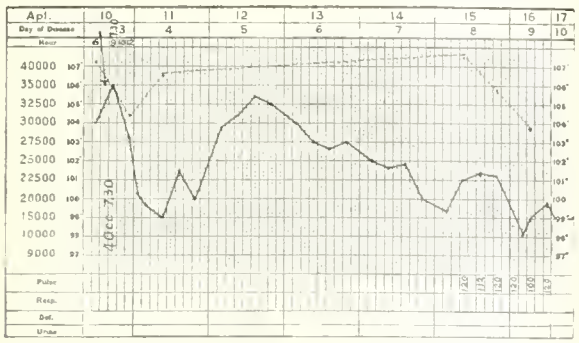

CHART 5.—Dotted lines show leucocyte levels. Arrows indicate points at which serum was given. Figures indicate amounts of serum in centimeters.

sixth day, four died. He concluded that the serum exerted a specific influence and should be used early in the course of the disease. The results on the cases of septicemia were especially striking. One patient with between 2000 and 3000 colonies to the cubic centimeter before treatment had but twenty-one colonies to the cubic centimeter the day after the administration of the serum. None were obtained in subsequent cultures or from the blood or organs post-mortem. This feature of the effect on the organisms in the circulation has been noted by Cole also, all of his cases being bacteria free after treatment. Against the use of polyvalent serum it may be argued that the antibodies against the individual strains may be relatively lower than when a single typical strain is used for immunization, and further, that although the several strains of a polyvalent vaccine may differ morphologically and culturally, they may be identical from an immunilogical point of view.

It has been shown by Neufeld that the various types of the pneumococcus may be identified by protection experiments, using immune sera prepared against the different strains. Mice were injected with several times the lethal dose of virulent pneumococci and a short time after were given a dose of immune serum. If, however, the period between the injections were prolonged or if the dose of pneumococci was very large no amount of

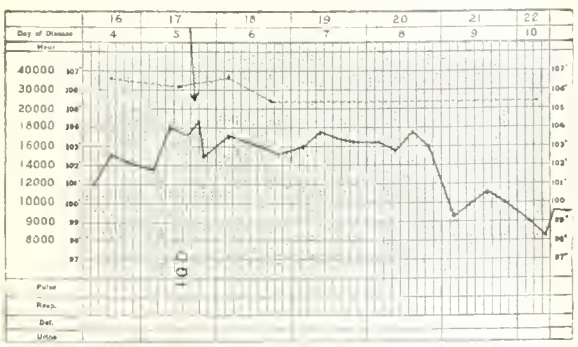

CHART 6.—Dotted lines show leucocyte levels. Arrows indicate points at which serum was given. Figures indicate amounts of serum in centimeters.

serum would protect. For agglutination tests mice were injected intraperitoneally. The peritoneal exudate is available in four or five hours.

Working along these lines, Cole and his coworkers have divided the pneumococci into four groups, which he classifies as types 1, 2, 3, and 4. Type 1 includes organisms causing almost 50 per cent. of our pneumonias and capable of producing an immune serum which protects against and agglutinates only members of this group. Type 2 contains organisms causing a smaller number of cases of a more severe type and capable of producing a serum specific for this group. Type 3 is the *Streptococcus mucosus*. Type 4 includes all organisms not agglutinated by sera specific for types 1 or 2. Immune sera have been prepared by Cole against some of these types, and are now being used in suitable cases.

The basis for the work on the immunology of pneumonia was the observation made by Fraenkel that animals that had been infected with pneumococci and recovered were immune. G. and F. Klemperer showed that the blood of immunized animals had protective properties and that the blood of patients recovered from pneumonia would protect rabbits against infection with the pneumococcus.

Some workers have failed to demonstrate this protection, but working with classified types Dochez has found it present especially after the crisis. It appeared much earlier in patients treated with specific serum by Cole than in untreated cases.

The mechanism of recovery and protection is uncertain. The original theory of an antitoxic action similar to that obtaining in diphtheria has been abandoned, as no one has been able to show that the pneumococcus produces toxins corresponding to those demonstrated for the diphtheria and tetanus organisms. No direct bacteriolytic action has been demonstrated. Neufeld claims that bacteriotropins favoring phagocytosis and digestion constitute the only factor so far definitely established. These bacteriotropins he discovered in pneumonia in 1904, about the time that Wright demonstrated opsonins in normal blood. The properties of both are similar if not identical. These bacteriotropins so alter virulent pneumococci that they are readily taken up by the phagocytes. As the final digestion is accomplished by the leucocytes, their importance in the mechanism of recovery will be easily appreciated.

Conclusions: Striking as were the abrupt terminations of the disease on the administration of the serum in two of our cases, the probability that they were merely coincident with a natural defervescence must be borne in mind. It would be a satisfaction to think that in the cases having chills the serum had furnished bacteriotropins enough to cause phagocytosis and consequent lysis of the pneumococci. In this way enough endotoxins to cause the disturbance might be liberated. This disturbance might be likened to the pseudo-crisis which occasionally occurs near the termination of a pneumonia. The reactions did not seem to be anaphylactic in nature. To the patient who had shown the most marked reaction a second dose (50 c.c.) was given three days later with no result.

However, so many factors enter into the interpretations of the result of therapy with a polyvalent serum that speculation is profitless. Until our knowledge has progressed attention should be confined, as Neufeld and Haendel advise, "to the action of high value serum on typical cases only until value in typical cases has been established. Strains from cases resisting treatment should be identified and classified."

276 WEST SEVENTY-THIRD STREET.

A CASE OF SIGMOID DIVERTICULITIS SIMULATING MALIGNANCY:

DEMONSTRATED BY RADIOGRAPH; OPERATION AND SPECIMEN.

By ROBERT ABBE, M.D.,

NEW YORK.

A LAWYER, aged 60 years, had a short attack of sigmoid colitis, so called, during the past summer, followed by loss of weight, from 168 to 146 pounds.

In March, 1914, a rather sudden partial obstruction

FIG. 1.—Bismuth enema. Inconclusive narrowing of the sigmoid.

occurred with acute tenderness over a hard resisting mass in the left iliac fossa. Temperature 101°, leucocytes 22,000, polymorphonuclears 80. From this he recovered in ten days, by enemas and rest, a small hard mass remaining fixed in the left iliac fossa.

Diagnosis between neoplasm and diverticulitis being

FIG. 2.—Four days later. (Picture reversed as the plate was placed against the abdomen.) Bismuth remains in the liverticula after all other bismuth was eliminated.

difficult, a bismuth injection was given and a radiograph taken by Dr. Lewald, but only a narrowing of the sigmoid shadow which was irregular in outline was shown to suggest new growth. Dr. Lewald suggested a bismuth meal as more likely to demonstrate the nature and seat of obstruction by distending the dilatation from above.

On the third day after the colon bismuth injection

FIG. 3.—Second day after bismuth meal—old and new diverticula shown, with bismuth.

had been eliminated, a meal was given and a radiograph taken at once. To our great surprise the picture showed round spots of bismuth in the affected area of the sigmoid unlike any remnants of ordinary bismuth injections not yet eliminated.

Numerous serial radiographs were taken during successive days, following the bismuth meal, and in every one up to the tenth day the same round spots remained unchanged, although the meal and the injection had been long since completely discharged.

There were groups of two and three and several single round bismuth shadows always in the same anatomic situations. These admitted of but one interpretation, namely, bismuth fluid retained in diverticula of the wall of the sigmoid.

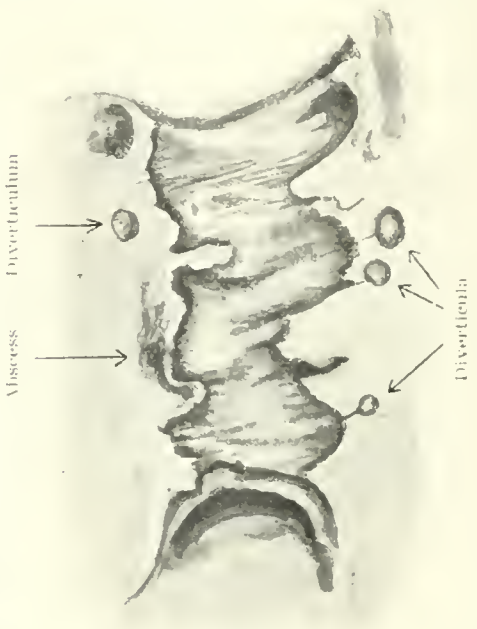

FIG. 4.—Section of the sigmoid mass through the thickened mesentery, diverticula and abscess shown.

Operation was done April 4 as for a left inguinal colostomy. A loop of the sigmoid was drawn outside the abdomen and a hard dense mass found in the wall

and adjacent mesentery with adhesions to the fossa. With much care this was loosened and two enlarged lymphatics found in the adjacent mesentery. Microscopic study of these showed inflamed lymph nodes without malignancy. The mass, however, had a suspicious feeling, being, in gross, as large as a small pullet's egg, but not involving the anterior wall of the sigmoid.

Search was made for diverticula, and many were easily demonstrated. Any one would have held a small white bean, but no fecal contents were in them. They were rather like pockets with large and small openings into the bowel and contained only gas.

A large loop of bowel was brought outside the abdomen and stitched there, for resection later.

On the fifth day under gas anesthesia a five-inch piece of bowel was removed and a Dupuytren clamp applied to the spur of the adjacent loops. This came away a few days later and the usual closure followed uneventfully.

The specimen removed was distended by formalin and hardened in the same, so as to dilate any pockets in the diseased part.

The picture shown later was a brilliant demonstration of the efficiency of bismuth picture showing diverticulitis, inasmuch as each group of shadows was situated precisely as shown in the sigmoid specimen.

It is difficult to demonstrate all of these in one section, but by a probe passing into each one from the mucous side before cutting through it—all were identified. One sample shown is characteristic of all. One diverticulum had formed an abscess in the mesentery outside the intestinal wall. Serial sections throughout the inflammatory mass showed no trace of malignaney.

Two other striking illustrations of intestinal diverticulitis have come under my care, and are worthy of brief record on account of the new interest of the subject.

The first occurred fifteen years ago in a man who had vague left iliac pains. Exploratory laparotomy showed the sigmoid free and uninflamed but studded with several growths like mushroom vegetations, fairly uniform in size and averaging the size of a small bean. Diverticulitis was then unknown and I supposed I had to deal with multiple malignant growths dependent on some hidden pelvic tumor, but on pressing them I found each one contained gas and discharged into the intestine with a pop, showing that not one of them had fecal contents. In this way I emptied most of them and inverted the peritoneum over one of them with a stitch, but saw no reason to do anything else. The patient recovered.

The second case was in a man who had sudden and complete obstruction of the sigmoid at the upper edge of the pelvis—after months of intestinal colic of varying degree. I was called upon to make a left inguinal colostomy to save his life. He insisted on a later operation to resect the supposed cancer obstruction. With the assistance of Dr. Frank Hartley and Dr. Schley, I made a median exploratory opening and found a dense growth adherent to the promontory of the sacrum and the hollow below. Most painstaking inspection with every opportunity to study it convinced us all that it was not only malignant but inoperable. We gave a bad prognosis.

After two years he remained well except that there had been a general septic arthropathy following the onset of his trouble, and no malignant development followed.

The patient now insisted on another attempt to close the fistula. Dr. Hartley operated and now found a less dense and more movable mass which he was able to resect. Time had removed the inflammatory products about the mass.

Study of the mass now showed typical diverticulitis with abscess of the wall. The patient has maintained his health now for a period of five years after the operation except for his stiff joints.

13 West Fiftieth Street

ULCER OF THE LESSER CURVATURE.*

By J. RUSSELL VERBRYCKE, JR., M.D.,

WASHINGTON, D. C.

INSTRUCTOR IN GASTROENTEROLOGY IN THE MEDICAL DEPARTMENT OF GEORGETOWN UNIVERSITY.

Gastric ulcer at some distance from the pylorus differs considerably from pyloric and duodenal ulcer both as regards symptomatology and treatment indicated. Often the location of the ulcer is not accorded sufficient importance in giving advice to the patient.

With our modern methods of localization we are learning that ulcers of the lesser curvature of the stomach are quite frequent. Brinton's statistics, which have been quoted for some years in the textbooks, showed that 27 per cent. of gastric ulcers were on the lesser curvature. Welch found 288 out of 793 ulcers to be in this location while on the other hand Osler states that 90 per cent. of gastric ulcers are at the pyloric end. This last statement certainly does not correspond with what we are finding at the present time.

The thread test and the radiograph afford us the only reliable means of localization of ulcer. It has been said that the longer the length of time after meals before the pain appears the further from the mouth is the ulcer. This is true in many cases and usually serves to differentiate duodenal from gastric ulcers, but it has been recently shown by Einhorn that this rule is by no means invariable. It is certain that in gastric ulceration the time of appearance of the pain is no indication of the position of the lesion. In fact many patients do not have pain as will be shown later.

In the last two years I have had twenty-five cases of ulcer of the lesser curvature definitely localized. I have reviewed the histories of these patients with reference to the probable duration of the ulcer, the principal symptoms and diagnostic signs present. There were all ages represented, the age incidence corresponding to that of ulcer generally. The duration was from four months to twenty years, the average being a little over six years.

Pain was present at the time of examination in but fifteen out of the twenty-five patients. Three had had pain in the past while seven had no pain at all. Of those having pain two complained of pain immediately on swallowing; four in fifteen minutes; one in a half hour; one in one and a half hours; and in six the pain was of a very indefinite character. This is rather interesting in view of the general statement made in most of the latest textbooks that pain is the most characteristic symptom of ulcer of the stomach and that it appears immediately after meals.

It may be stated that, as a rule, the pain in ulcer of the lesser curvature is not apt to be as severe or as characteristic as that accompanying ulcer at the pylorus and that the time of appearance of the pain is not a reliable index as to its position.

Nine of the series vomited. Five others had vomited at some time in the past but eleven had never vomited. The vomiting that occurs in ulcer of the lesser curvature is due as a rule to the irritative effect of the ulcer while that in pyloric ulcer is apt to be the result of obstruction, occurs a longer time after meals, and in larger amount.

*Read before the Georgetown Clinical Society, March 17, 1914.

Pylorospasm, with consequent vomiting, can occur, however, with ulcer at a distance from the pylorus.

Nausea was found to be somewhat more frequent, being present in twelve, while in six it was very rare or slight. Two used to have nausea and five never did.

Heartburn was complained of by eleven; five had it very slightly or had it in the past; nine were never troubled.

Twelve had pyrosis; in three it was rare; ten never had it. Eleven had acid regurgitation.

It may be seen that the foregoing symptoms were present in about the same number of patients. They are in nowise characteristic of the condition and are far from constantly found.

A certain periodicity of symptoms was noted in nearly all of the patients but was not as clean cut or marked as is the case in chronic pyloric or duodenal ulcer in which cases it is almost diagnostic.

Eighteen patients had lost weight varying from a few pounds to sixty pounds. In six the weight was stationary while one had gained.

The stomach contents were examined after a test breakfast in twenty, the hydrochloric acid being high in twelve, normal in six, and subnormal in two.

A spot of localized tenderness was found in twenty-one patients and absent in four. The tender point, then, seems to be far more constant than any of the subjective symptoms. It does not, however, seem to be necessarily directly over the ulcer and may be found in nearly any part of the epigastrium. In eleven, the largest number, it was found in the mid-epigastrium; it was just below the xyphoid in three; on the right side in five, on the left side in one, and not well localized in one. A dorsal spot was found in but three of the twenty-five patients.

In ulcer generally the writer believes occult blood in the bowel movement to be probably the most important single sign. It was present in this series in twenty-two and absent in but three. Examination at intervals will show it present at some time in practically every case.

FIG. 1.—The thread test.

FIG. 2.—Showing marked incisure at A

FIG. 3.—Spasmodic hour-glass contraction at A.

We now come to a consideration of the two methods which, in addition to helping us with the diagnosis, afford us the only means of localizing the ulcer, the thread test and the radiograph.

The thread test was tried in twenty-four patients in twenty-one of whom it was positive and in three negative. Most of the patients had repeated tests as it is the safest plan to give two or three tests and compare the threads before drawing conclusions from this test.

FIG. 4.—Spastic defect in filling of the antrum (A) and the duodenal cap (B).

A thread smeared over a considerable length is of no value (see Fig. 1). It may indicate profuse bleeding from an ulcer but it is just as likely to mean that the gastric mucosa is congested and soft, bleeding at the slightest touch, as do the gums at times. When the thread is covered with blood over a considerable area it is my custom to give the patient one drop of a 25 per cent. solution of silver nitrate in a whole glass of water immediately on awakening for several mornings and then repeat the test. At this time the thread will usually be negative unless the bleeding is due to an ulcer in which case there is apt to be a localized mark. The test should then be repeated once more to determine if the mark is in the same place.

Several threads all marked at the same point are good evidence of the existence of ulceration. I have never known this to fail. There are two varieties of threads which are most characteristic of ulcer. In one there is a stain corresponding to the full length of the ulcer while in the other there are two small marks a short distance apart, with a clear interval, the stains representing the rim of the ulcer and the clear space the crater. Ulcers on the lesser curvature are indicated by stains from forty-four to fifty-four centimeters from the teeth.

Fifteen of these patients were radiographed. The results were entirely negative or indefinite in but two patients but on the other hand in but seven cases would it have been possible to have localized the ulcer from the radiograph alone. As a diagnostic aid and to determine the results of ulceration the radiograph is of the greatest value, but it is in probably 50 per cent. of the cases distinctly inferior to the thread test in localization.

Four of the fifteen patients showed a typical incisura (see Fig. 2), or notch in the greater curvature, which is like a finger pointing to an ulcer on the lesser curvature directly opposite. This is our best sign of ulcer of the lesser curvature but unfortunately it is not constantly found. It has not been many months that we have known of the significance of the incisura but now regard it as the strongest confirmatory evidence of ulcer of the lesser curvature, though Case has reported instances of duodenal ulcer in which an incisura was present on the greater curvature. I have suggested the advisability of making pressure over the stomach, the duodenum, the appendix, and the gall bladder at the time of the fluoroscopic examination to see if an incisura could be reflexly produced thereby. Dr. Christie in adopting this suggestion has succeeded in producing a typical incisura in one patient by pressure on the appendix. This seems to me to be a most valuable method in interpreting our findings.

Two of the patients presented typical organic hour glass stomachs caused by ulcer of the lesser curvature. Both of these patients had perforated, one being a chronic perforation into the gastrohepatic omentum, and the other an occult perforation which was shown at operation to have been sealed up by perigastric adhesions, flush with the stomach.

The seventh patient in whom the x-ray localized the ulcer had a spasm completely encircling the stomach, a spasmodic hour glass which exactly corresponded with a definitely localized spot on the thread (see Fig. 3).

The remaining six patients had a reflex spasm of the antrum pylori and duodenal cap (see Fig. 4) which was merely confirmatory of the existence of an ulcer or other focus of irritation but which did not help in the localization.

Why nature should set up a spasm at a point distal to the ulcer is not clear. The interpretation of the spasmodic defects of filling of the pylorie part of the stomach and the first part of the duodenum is the field in which there is the greatest need for elucidation. We are less sure of our findings in this location than in any part of the digestive tract.

FIG. 5.—Left-sided drain-trap stomach, due to spastic contraction of the longitudinal muscle fibers, in a case of ulcer of the lower curvature.

There is probably less liability of an ulcer on the lesser curvature becoming so markedly indurated as one at the pylorus, probably because of its being so situated as to be less irritated. In-

durated ulcer certainly does exist in this location, but on the other hand there can be little doubt that there may also exist a chronic mucus ulcer, softer in character, and which may be impossible of palpation through the unopened stomach.

At operation on several of my patients it has just been possible to palpate the ulcer. Except for the slightest thickening it would not have been felt. In two other patients the ulcer could not be found but there is not the least doubt in my mind in view of the evidence that the lesion existed. These histories will be given.

Case I.—Mr. W. H. F., age 40, was referred to me November 25, 1913, by Dr. Constas. His principal complaints were mental in character, consisting of depression by melancholy, with a fear of going out of doors by himself or even staying in a closed room by himself. He had, however, twelve years before had severe cramps in the epigastrium and had attacks of indigestion ever since. His history was very unsatisfactory. Physical examination was entirely negative. The appendix and cecum could both be plainly palpated, but there was no tenderness anywhere. Examination of his stomach contents after a test breakfast showed some hypersecretion and free HC1 42 with total acidity 62. Two examinations of the stool on meat free diet showed occult blood. The first thread test was strongly positive, but not localized. A second showed a well marked stain from 54 cm. to 55 cm. from the teeth. A third thread was marked at exactly the same place and seemingly showed the rim of the ulcer.

In view of the positive threads and the occult blood the patient was radiographed by Dr. Christie. This examination showed defective filling of the pyloric part of the stomach and cap. Operation was advised and performed by Dr. Constas, who was unable to detect the ulcer or any other abnormality but a gastro-enterostomy was performed. He subsequently gained twenty pounds in weight, has gone to work for the first time in years and has lost his fears.

Case II.—Mr. R. M., age 32, was referred to me July 2, 1913 by Dr. Prentiss Willson. Four years before he had, while in a mining camp, been seized with severe abdominal cramps which were said to be due to appendicitis and he was operated upon. He said that he has had the same pain in typical intermittent form ever since that time. In between the attacks, which would last for some weeks, his health and digestion would be excellent. His present attack had lasted for several months and was characterized by extreme soreness in the epigastrium, "like a cancer sore in the mouth," vomiting, acid regurgitation and constant pyrosis. He had had a typical boring pain in the epigastrium starting in from fifteen minutes to a half hour after meals and relieved by alkalies or vomiting.

Physical examination disclosed a slightly tender point in the mid-epigastrium and another point of great tenderness one-half inch to the right of the navel. Gastric acidity was 44 and 56. There was a faint reaction for occult blood in the stool and a strongly positive thread test.

Gastric ulcer was diagnosed, but he was allowed to go West on business. He returned in October after having had a terrible time with his stomach all Summer. At this time repeated thread tests were positive. His tenderness was the same as before and a spastic pylorus could be rolled under the fingers. Radiographic examination by Dr. Christie showed the stomach to be hypotonic with slight ptosis, of average size with fair peristalsis and no incisura. There was a marked spastic spastic defect in filling of the antrum.

The patient was put on an ulcer treatment with marked improvement so that for a time his stomach felt good and the thread test was negative, but after a month and a half, during which time he had been under a constant nerve strain, he had a return of marked burning, with a tender palpatable pylorus. At this time he was seen by Dr. Morgan in consultation, who unreservedly confirmed the diagnosis. Operation was advised and was performed by Dr. Peck at the Roosevelt Hospital in New York. I understand that Dr. Peck agreed with the diagnosis but at operation was not able to demonstrate anything wrong with the stomach, duodenum or gall bladder, though he did find a band at the cecum which partially rotated this part of the intestinal tract.

It would seem advisable in cases such as these, where there is a question as to the correctness of the diagnosis, to make a small opening in the stomach and insert a gastroscope, as has been practiced by several surgeons. Such a procedure would not increase the mortality and would have two distinct advantages. It would enable us to be certain of the diagnosis in the particular case and so enable us to treat the patient with more intelligence and it would help in our diagnosis of future cases.

In this small series none of the patients had large hemorrhage as a complication and indeed only one had had hematemesis in the past. Two of the patients, however, had perforation.

The prognosis for the cure of ulcer of the lesser curvature by medical means is as good or possibly a little better than that for pyloric ulcer, but surgery, with the most universally employed measure, has not accomplished its best results in ulcer in this location.

It is the opinion of those with the largest experience that gastroenterostomy not only can not be expected to cure these cases but is often detrimental. Excision of the ulcer is certainly the operation of choice for ulcer of the lesser curvature which has resisted medical treatment. Most surgeons hesitate to attempt excision, however, since the ulcer is difficult of access and the surrounding tissue liable to be friable so that the fear of high mortality intimidates them. Those who have mastered the technique and are doing this operation report brilliant results. Coffey is one of the pioneers in this line and for some years has been advocating and practicing excision by a method of his own.

Eight of my series came to operation and in only one was the ulcer excised. This operation was performed by Dr. Martell and though an extraordinary amount of work was necessitated by the complications, a perforation and nearly complete hourglass contraction, the ulcer was successfully excised and there was no more shock than after a simple gastroenterostomy. This patient has not gotten an ideal result as for some reason she has a spastic contraction at the site of the old organic contraction, as shown by the radiograph, but there is no occult blood or pain, and it is questionable as to what it is due to. I do not consider that it militates against the operation of excision. With increasing experience and the development of a good technique the mortality should become as low as that of gastroenterostomy and the end results infinitely better.

Although I have never seen Coffey's operation performed it has appealed to me greatly and I shall quote from his summary of the description of the operation.

"In order to do good stomach surgery it is necessary to determine the extent and location of the ulceration. This can be done properly, as a rule, through an incision in the stomach wall and when clamps are not used.

"The incision should be ample and should usually be made transversely to avoid the vessels, after which the inside of the stomach should be seen. By the use of deeply placed traction loops the anterior wall of the stomach is lifted, the gas in the stomach comes to the top and escapes when the incision is made, thus relieving intragastric pressure. The fluid now immediately gravitates to the lower levels of the stomach cavity, from

which it may be dipped and sponged with deliberation. After the stomach is thus emptied and the cavity dried, the inspection of the mucus membrane is easy and the mystery and difficulties of stomach surgery vanish; for the surgeon, after opening the omentum above and below the stomach and packing the lesser peritoneal cavity with gauze, proceeds to trim out the diseased portion with the same precision and completeness with which he would amputate a leg for gangrene or remove a breast for cancer. . . ."

THE ROCHAMBEAU.

PRIMARY CARCINOMA OF THE VAGINA TREATED BY RADIUM AND ROENTGEN RAYS.*

By ISAAC LEVIN, M.D.,

CHIEF OF THE DEPARTMENT OF CANCER RESEARCH, THE MONTEFIORE HOME, ASSOCIATE IN CANCER RESEARCH, COLUMBIA UNIVERSITY

PRIMARY carcinoma of the vagina is a comparatively rare clinical condition. In accordance with W. Rogers Williams[1] less than 1 per cent. of all cancers in women are of vaginal origin. This is the more remarkable since in the adjacent uterus carcinoma occurs very frequently, and this uterine carcinoma just as frequently spreads into the vaginal wall. Furthermore the wall of the vagina is subjected to various irritations more than any other organ in the body. Apparently there is in this instance another clinical proof of a contention indicated by the writer[2] as a result of his experimental work that the different organs have a different innate susceptibility to the formation of a primary malignant growth.

Primary carcinoma of the vagina appears as either a papillary tumor or an excrescence with a broad indurated base which is most frequently attached to the upper part of the posterior wall, or else it occurs as a diffuse infiltration which may completely surround the vagina and constrict its caliber.

The subjective symptoms of the disease are identical with those of the carcinoma of the uterus; namely, hemorrhage, foul vaginal discharge, pain in the pelvis, the rectum, the bladder, or along the sciatic nerves.

The results of surgical treatment of this condition are extremely unsatisfactory. Some twenty years ago Schwartz[3] stated that the prognosis and the results of the radical operation of the carcinoma of the vagina are absolutely bad. There is practically not a single case cured. J. Bland-Sutton[4] writing as late as 1911 states as follows: "Surgery can do little in cancer of the vagina, for even in the very early stages free removal may anticipate some of the evils of the disease by establishing a vesical or rectal fistula."

What is the reason for the failure of surgery in this condition? The beginning of the spreading of carcinoma takes place through the lymphatics into the nearest regional lymph glands and a radical operation always implies the complete removal of these lymph channels. Bruhns[5] and others have shown that the vaginal wall is extremely rich in lymph vessels, and the latter serve at the same time the uterus, the bladder, the rectum, and the rest of the pelvic tissues. As a result all these organs and tissues very early become involved in the disease. As a consequence the carcinoma recurs after an operation even when the incisions are made within the healthy tissue apparently far away from the original growth. Very recently Wertheim,[6] Veit,[7] and others recommend in every case of the carcinoma of the vagina to do an abdominal operation and remove the uterus, vagina, and all the pelvic lymph glands. Up to the present no estimate can

*Case and microscopical specimens presented at the Section on Obstetrics and Gynecology of the New York Academy of Medicine on May 26, 1914.

FIG. 1.—Epithelioma of vagina, before radiation. (Low power.)

be made whether this method will actually improve the results of the surgical treatment of the disease.

A priori a primary carcinoma of the vagina must be considered a favorable condition for radium and Roentgen ray therapy. It is comparatively easy to place the radium tube in complete approximation to the diseased part. The vaginal wall is thin and it is consequently quite possible for the rays to reach the lymph vessels and even the adjacent glands. In view of the general rarity of the condition there are few cases reported up to the present which were treated with the rays. G. G. Ward, Jr.,[9] reported in 1908 a case of primary epithelioma of the vagina treated by radium without success. His technique was faulty and at least 40 times greater a quantity of radiation should have been used in the case. The London Radium Institute[7] reported 11 cases of carcinoma of the vagina and the vulva treated by radium of which 6 cases were improved. Griffith[10] reported a case of primary epithelioma of the vagina treated by radium, which is apparently cured.

The present case of the writer seems to be the only one in the literature where microphotographs of slides taken before and after treatment are presented.

The patient, Mrs. G., age 59, widow, had one child at the age of 24. On April 24, 1913, she was admitted to the German Hospital, service of Dr. Seeligmann where a diagnosis was made of primary carcinoma of the vagina. A piece was excised for microscopical examination which showed a squamous cell epithelioma (Fig. 1). The condition was considered to be inoperable and the patient was discharged. For a time the patient was treated by Dr. Kessler with hypodermic injections of selenium, and on February 27, 1914, she was referred to me by Dr. Seeligmann and Dr. Kessler for radium treatment.

The patient appeared emaciated, weighed 115 lbs., complained of continuous bloody fetid vaginal discharge, constant backache, pain on defecation, rectal tenesmus, painful and frequent micturition. She was urinating from 5 to 6 times a night. On examination the labia and vulva appeared normal with the exception of the presence of sanguineous fetid discharge. On separating the vaginal walls there was noticed, beginning about $1^1/_4$ in. from the introitus vaginæ, an ulcerated area which circled around the whole vaginal wall, but appeared to be deeper on the posterior side. The margins of the ulcer were indurated and the surface consisted of friable tumor tissue, which was very easily detached. The vaginal canal was so constricted by the ulceration that one finger could hardly pass through. As the examination was very painful no attempt was made to determine the upper margin of the ulcer. Rectal examination showed that the mucous wall of the rectum was not involved in the growth and the uterus appeared normal. A narrow strip of soft and apparently normal vaginal tissue was felt between the ulcerated area and the cervix uteri. The right uterosacral ligament appeared thickened, infiltrated, and hard, but no lymph glands could be felt anywhere in the pelvis. The inguinal glands were not enlarged.

The patient received 8 applications of radium of 12 hrs. duration each with an interval of 36 hrs. between the applications. The amount of radium salt used was 50 mgm. The tube was screened with 0.5 mm. of silver, 0.75 mm. of gold and layers of photographic paper to protect against the caustic action of the secondary rays. The whole was enclosed in a sterile rubber tube. At the same time the treatment was supported with massive doses of *x*-rays in accordance with the technique and by the aid of the apparatus devised by Kroenig and Gaus of Freiburg. While the radium was applied directly to the ulcerated area of the vagina, the *x*-rays were applied through the abdomen and through the back in order to influence not only the vaginal condition but also the uterosacral ligament and any of the glands which it was possible to reach.

In all 10 *x*-ray treatments were given. The rays were sent through 4 fields on the abdomen and through 2 fields on the back. Their combined quantity equaled 480 X as measured by Kienboeck photographic strips.

At present the patient has no vaginal discharge, no backaches, no rectal discomfort and no frequency or pain on micturition. She gained 15 lbs. and is able to attend to her household duties.

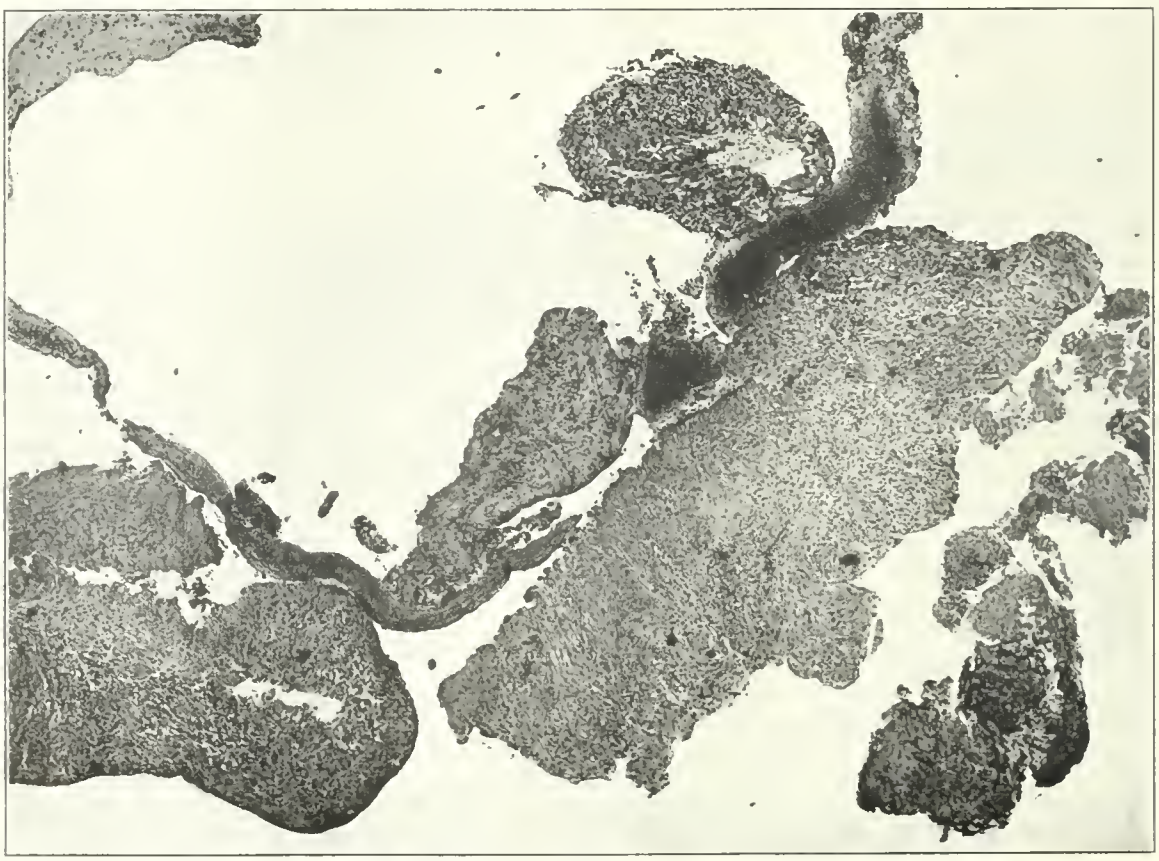

Fig. 2—Epithelioma of the vagina, after radiation. (Low power.)

Objectively the vaginal wall presents at a distance of 1¼ in. from the introitus vaginæ an annular indurated scar-like mass, the canal is even more contracted than when the treatment began. The surface of it is smooth and not friable. A piece was excised for microscopical examination throughout the whole thickness of the vaginal wall. The piece was taken from the right lateral wall on one hand in order to be nearer the right uterosacral ligament and on the other hand not to injure the bladder or the rectum. A microscopical examination of the piece showed absence of cancer tissue, the latter being replaced by a connective tissue and round-cell infiltration (Fig. II).

The condition of the patient is thus greatly improved both clinically and anatomically. The result is the more remarkable and gratifying since the condition was far advanced and inoperable before treatment began.

Primary carcinoma of the vagina usually runs a rapid course. The average duration of life in the cases collected by W. Rogers Williams is only 16.5 months. At the time of the first examination of the writer's patient it seemed that her end was very near. Now, three and a half months later, at the time of this writing, she has gained 17 pounds and feels perfectly well. (She has gained 2 pounds more since she was demonstrated to the section.) The future will show how permanent the improvement will remain, but a great deal was surely gained already.

A CASE OF VOLVULUS OF THE JEJUNO-ILEUM WITH ANTERIOR GASTRO-ENTEROSTOMY.

By WALTER E. TOBIE, M.D.,

PORTLAND, MAINE.

PROFESSOR OF ANATOMY, MEDICAL SCHOOL OF MAINE; VISITING SURGEON, MAINE GENERAL HOSPITAL.

Charles S., an Italian, aged seventeen, entered my service at the Maine General Hospital, March 8, 1914, for an emergency abdominal operation. From him and his mother, who accompanied him, a history was obtained to the effect that he had been ill some time previously with a reddening of the skin, and that two days before coming to the hospital he had suffered severe abdominal pain. Its character was described as sharp, doubling him up so that he could not walk. Early in the attack his bowels had moved and he had vomited a number of times, principally after taking castor oil.

Altogether, the history was fragmentary and not helpful. Desquamation of the hands and feet in connection with the history of erythema indicated that he was convalescing from scarlet fever. His appearance and the examination of the abdomen pointed urgently to immediate operation.

The abdomen was rigid, tender in the left upper and right lower quadrants, and not distended. The pulse was 130, of feeble character; the temperature 97°, and the general aspect that of a poor surgical risk. He was prepared for immediate operation and a McBurney-Weir incision made, through which there was removed an appendix, the appearance of which was in no sense bad enough to account for his condition. The peritoneal fluid was somewhat in excess of normal and exploration showed a mass in the upper left quadrant. The appendectomy incision was closed and an L incision made above the umbilicus. In the upper left portion of the abdominal cavity, the omentum was found matted about a mass of intestine, which proved to be a twisted loop of jejunoileum. On freeing the volvulus about a foot of gut appeared, reddened, inflamed, and markedly thickened. So thick was its wall as to make the future patulency of its lumen a matter of grave doubt. The thickened part extended up and included, somewhat, the last portion of the duodenum. Manifestly, a resection was impossible, and with the somewhat faint hope that the lumen might remain sufficiently patent to serve as a duct for the hepatic, pancreatic, and duodenal secretions, an anterior gastro-enterostomy was made. A loop of intestine, about two feet from the duodenum, was anastomosed to the ventral wall of the stomach and the abdominal incision closed.

The immediate after-treatment was strychnine 1/30 grain every three hours and caffeine 1 grain every four hours, hypodermically, with salt solution into the rectum by the Murphy drop method. A moderate amount of water was given by mouth and morphine hypodermically in ¼ grain doses as needed. The pulse rate increased and the temperature rose, recording in twenty-four hours 160 and 100°, respectively. The

patient during the second day vomited large amounts of bright green bile and the bowels moved, seemingly in response to the hypodermic administration of pituitary extract. On the third day he passed large amounts of gas and feces, at times involuntarily. His temperature rose to 101.6° in the axilla.

During the fourth, fifth, and sixth days he suffered intense pain about the upper incision, his appearance and symptoms indicated sepsis, and his mental condition was bad. Vomiting and involuntary defecation occurred frequently. On the seventh day the incision opened and discharged dark broken-down material, gangrenous in odor and appearance. From this time on, he improved rapidly, ate soft solids on the eleventh day, sat up on the fourteenth day, and left the hospital on the twentieth day.

An *x*-ray photograph taken six weeks after the operation shows the success of the anastomosis. The plate was exposed immediately after the patient had been given three ounces of bismuth subcarbonate in cereal. Apparently the duodenum and first part of the jejunoileum serve only as a duct for the passage of the digestive secretions which empty into them, and food passes from the stomach through the new opening. The patient declares himself entirely well and experiences no discomfort except an occasional twinge in the abdominal wall. He eats everything without distress and his bowels move daily without laxatives.

Regarding the outcome of the case, if the gastro-

enterostomy had not been made, I believe it may reasonably be contended that death would have resulted. I have previously encountered a gengrenous loop of the extreme upper part of the jejunoileum, due also to volvulus. Here no attempt was made to anastomose, and it is apparent that such an operation would have been useless, barring the possibility of a regurgitation of the secretions through the pylorus taking place without gastric disturbance.

Impairment of this portion of intestine to a degree short of gangrene may not be immediately fatal without gastroenterostomy, but it presents the likelihood of future constriction and obstruction with disastrous results, which the operation obviates.

AN APPARATUS FOR NEUROVASCULAR TRAINING.

By SIMON BARUCH, M.D.,

NEW YORK.

I HAVE coined the term Neurovascular Training to denote a procedure by which the nervous and vascular structures of the skin may be gradually accustomed (trained) to accept increasing stimulation of their activity by response to excitation from temperature and friction conveyed by water. By this method the so-called shock from cold water is avoided.

Perhaps the chief reason for the lack of appreciation of the remedial value of water is the indefinite application of this agent. Water must be applied as are medicinal agents, *i. e.* with precision of dosage. In my work on "Hydrotherapy" (William Wood & Co., New York) this point is elaborated.

To facilitate the application of water in many chronic diseases requiring tonic or restorative effects, I have devised a simple douche apparatus, by means of which the temperature, duration, and pressure may be arranged with precision for purposes of exact doses. The apparatus is here illustrated. It may be secured on the wall of a douche room constructed of waterproof walls and floor, size 8′ x 12′, on the left of its entrance. The patient standing at the other end receives the douche first upon the posterior part of the body and later upon the anterior part of the body, from the doucheur who stands at the opposite end grasping the nozzle. Before the patient enters the room the attendant arranges the temperature and pressure prescribed. He then places the patient in position and administers the douche. The direct stream is called the jet douche; by holding the point of the index finger of the hand which grasps the nozzle over the opening, the stream will form a fan. This is the milder form of douche—fan douche.

The middle of the floor must be covered by a slatted walk 2′ wide and 12′ long, upon the distal extremity of which the patient stands. This prevents his walking on the wet floor. After treatment he is dried, rubbed, and sent into the open air.

The douche may be administered daily or less frequently, the former being the most useful. The effect is enhanced by a preceding warming of the skin either by wrapping the body snugly in woolen blankets for a half hour or longer or by exposing the patient to hot air or electric light in a box arranged for that purpose. The first treatment is given at a temperature of 95° F.—20 lbs. pressure and one minute duration. The patient is dried, rubbed, and sent into the open air; on the following day the temperature is changed to 93° F., on the next following day to 90° F. This daily reduction of temperature is continued until the lowest temperature the patient is able to respond to without uncomfortable chilling after he goes into the air and exercises is reached and so continued. If at any time persistent chilling is produced, the treatment may be shortened one-half or less and gradually increased in duration and pressure. The chief point is that chilling may be obviated by increasing pressure and diminishing duration, never by increasing the temperature of the douche. The coldest douche under strongest

pressure is the most stimulating. A medium temperature about 70° F. to 60° F. of two minutes' duration and 20 lbs. pressure would give a more prolonged—a tonic—effect. The temperature of the water must never be lowered during the douche. Bearing these facts, which are the result of thousands of recorded treatments, in mind, no harm could come to the feeblest patient who is able to walk to the douche room. Whenever iron, strychnine, phosphates, or other tonics or so-called blood or nerve restorers are indicated, this neurovascular training will serve a far superior purpose in immediate refreshment and more rapid and enduring

tonic effect. The apparatus has been made for me by the Hydrotherapeutic Apparatus Co., New York City. Its cost is about one-fourth of that of the regular douche table.

The method most useful for neurovascular training at the patient's home is fully described in my work on "Hydrotherapy." It has succeeded when tonic drugs have failed.

CONSERVATISM IN THE TREATMENT OF DISEASE.*

By BEVERLEY ROBINSON, M.D.,
NEW YORK.

No one knows better than I how my title sounds to many ears among practitioners. They say in heart or by word of mouth, "We do not want to hear again the twice-told tale. We want something new, up-to-date, an advance over the old, well-worn, obsolete in medicine. Give us the new serums or vaccines to prevent or cure disease and not long-ago-medicines and formulas, that do not."

Is their claim desirable and true? In a way, it is. Of course, without trial—experiment of new things—how should we ever advance? Again, without enthusiasm, work, youth, how can we hope to have our wishes come to pass? How can we anticipate otherwise to banish pulmonary tuberculosis from the earth—throttle many acute diseases, protect infallibly against others? Isn't the use of antityphoid vaccine in the army, and even in private life, evidence sufficient to show how great is what we, the scientists, the real workers of to-day, have accomplished? Does not antitetanic serum again prove it? Why now be fearful of lockjaw after wounds from rusty nails, blank cartridges, toy pistol caps? How about poliomyelitis and the discovery of its cause and antidote, peroxide, and still more remarkable, the curative value of antimeningitis serum?

The familiar story of antitoxin in diphtheria, of salvarsan in syphilis, I shall not speak of. Nor again, may I more than allude to the prevention of malaria and yellow fever, simply with screens and the shutting out of the plague-carrying mosquito. Further, don't we know how flies carry many diseases? How fleas, bedbugs, and other insects infect us? How milk and water must be pure and not contain microbes of tuberculosis, typhoid, scarlet fever, what not? All this is true and glorious, and we laud and extol it immensely.

On the other hand, are we to free ourselves from the recognition that very many diseases are not prevented, cured, or even favorably affected by all the foregoing? We must recur to drugs, at least to a few simple or combined ones. We must have the sensible, watchful care of the good, old-time nurse, who could make the bed, empty slops, air the room, preserve peace and quiet in and near the sick chamber, and herself give the proper food in palatable form and attractively served, which the faithful doctor of many decades would prescribe. Added to this, came one or two prescriptions, that were at least inoffensive and made to conform to the stomachal demand of the patient, rather than to some vain theory of the imagination.

Nor should we be controlled by the daily outpouring of the various large manufacturing drug firms of Germany or our own country, or the lying advertisements of countless small druggists of our cities and towns. We also should know that much that is written in the medical journals is, after all, very crude and based upon very slight experience. It is given forth usually more to enhance the budding reputation of the writer and, of course, to bring patients, than with any belief that the world's knowledge is to be advanced. This is as it should be, perhaps, provided always it is properly governed and tempered in the end by wise men who have been through a similar experience.

One way to gain wisdom is to read occasionally the authors of long ago: Trousseau's "Clinic," Watson's, Aitken's, Niemeyer's, Flint's "Practice of Medicine," and note how little we have really advanced or even measured up to their wisdom in the treatment of ordinary diseases.

We must not believe either, that the new dosimetric alkaloids take the place of not a few old formulæ, the secret of whose efficacy we may not know, but the fact of their utility is sure and undoubted. Too many experiences and too many good and great observers vouch for it, and we should accept it without cavil or gainsay.

Take as an example from another viewpoint, the clinical effects of alcohol in disease, especially pneumonia and diphtheria. No matter what the laboratory reports now state, great clinicians like Todd and our own Jacobi, prove that in these diseases it is food and stimulant of the very best sort when life hangs as by a thread. I well remember when Dr. Edward G. Janeway was critically ill with pneumonia several years prior to his death, he owed his life essentially to the frequent taking of the best old brandy; and we must remember in the best Cognac we have not merely alcohol, but possibly ethers, which are very valuable additional stimulants. Surely this is true, and even more so, of some of the purest old wines of France, Spain, and Germany. The digestive organs and the powers of assimilation in a weakened state through acute disease, are strengthened actively and in a very remarkable degree (and far more than with any drugs) by their timely use.

It would be very easy to extend my statements, but perhaps in brevity is more force; and I wish above all to drive home, as it were, great truths of primary importance in the treatment of disease.

SOCIALIZATION OF MEDICAL TRAINING AND PRACTICE.*

By INEZ C. PHILBRICK, A.M., M.D.,
LINCOLN, NEBRASKA.

I MAKE no apology for departing from precedent in presenting a paper treating of medicine in its sociopolitical rather than technical aspect. Discussion of the fundamental social and political conditions that determine medical training and practice is certainly as important as that of a new "kink" or specific. Discussion in medical bodies and periodicals of the social relations of our profession is too generally individualistic in tone, putting professional good paramount to social good, a reversal of ethical order, or self-laudatory. It is well occasionally to consider the debit side of the account. An awakening social conscience forces upon the profession today recognition of the character of its function as one of social service, non-performance of which it cannot justify. Grave evils are charged

*Delivered before the Nebraska State Medical Society, May 12, 1914.

from without and admitted within the profession.

There are many unnecessary deaths due to defects in the physician's personality and training, and to irrational conditions that govern practice. Fortunate, indeed, that physician who has not realized his responsibility for a needless death, who has not sensed the burden of sorrow, irremediable loss, broken ambition, thus laid upon those who mourn. The death of a mother from puerperal sepsis, of a man or woman in the prime of usefulness, the victim of an operation unskilfully performed, a mistaken diagnosis, or faulty judgment in treatment—such disasters cry out for conditions of practice that would make like tragedies impossible. There is the vast economic loss entailed by the premature death of breadwinners; by the expense of unnecessary operations and courses of treatment; by prolonged invalidism due to inefficient treatment.

Again, under present conditions of practice, the physician is peculiarly liable to physical and moral deterioration. His work is very unequally distributed, entailing periods of undue stress and loss of sleep; and statistics prove his exceptional liability to drug habits that are subversive of health and morals. His professional relations draw him into a play—too often a clash—of personalities. The irritations and injustices of a competitive system of practice embitter his spirit and lessen his efficiency, if they do not warp his moral fiber. His work is largely uncensored by those qualified to judge of its quality. He can hardly escape the commercial taint which today permeates society. Following the lure of its false standards, he too often resorts to devious arts to increase income.

Efforts to uproot professional evils by legislative enactment, close organization, publicity, only harrow the surface. Present professional evils are not due predominantly to inefficiency; they are due to the irrational application of medical service. In true American fashion we add to our already absurdly large body of law, and go on in our lawlessness. We legislate against fee-splitting and leave operative the temptations thereto. Our profession is unique in that, though it supposedly aims at efficiency, it endeavors to bring within its organization as many as possible of those professionally unfit. Persons who imagine that honest and efficient medical service can be ensured by such a course are doomed to disillusionment. The A. M. A. can certainly do much to mitigate present evils by applying its large funds to the exposure of quacks and patent medicine frauds, the raising of professional standards, and the education of the public in matters medical. But to expect cure of those evils from within the profession is no more rational than an attempt to raise one's self by one's bootstraps.

The term socialization, as used in this paper, has no reference to any organized political movement, but implies the training, licensing, and salarying of all physicians by the State—State medicine. Though we may, by force of experience and use of reason, arrive at conclusions regarding a competitive system of medical practice identical with those reached by the socialist in considering a competitive system of industry, it were unfortunate if the bugaboo of a name were to militate against acceptance of such conclusions.

Sufficient analogies appear in the operation of other social functions, as our public schools, army and navy, postal service, and in State administration of the public health service and medical school inspection, to prevent one from being shocked by the idea of State medicine in its entirety. No discriminating person would for a moment abandon our educational system, based upon State and municipal school maintenance, with a salaried teaching body, for that chaotic condition, glimpsed by the least imaginative, wherein teachers were licensed to acquire their pupils and fees by whatever arts, graces, or deceptions at their command. And yet the closest parallel exists between public health and public education, which, together with moral rectitude, constitute the three chief assets of society. Disease should no more be tolerated than ignorance in a democratic state, founded upon the principle of the greatest good to the greatest number. Choice between literacy and illiteracy is not left to the individual: he is forced under instruction. Is it rational to leave to individual choice whether he be healthy or diseased? We have answered no in our installation of medical school inspection. One cannot imagine a nation so rash as to entrust the defense of its coast and merchant marine, and the enforcement of its will in international difficulties, to military and naval officers educated by the government, and then left to gather soldiers, sailors, and equipment, all to be paid from the pockets of those served. Picture the present Mexican situation under such circumstances! Surely the dove of peace would be hopelessly awing. What other community than one of the feebleminded would tolerate a police force feed by the citizens protected? What citizen therein would be certain of protection or free from unjust accusation? A brilliant present-day writer thus wittily and pithily characterizes the irrationality of our competitive system of practice:

"It is not the fault of our doctors that the medical service of the community as at present provided for is a murderous absurdity. That any sane nation, having observed that you could provide for the supply of bread by giving bakers a pecuniary interest in baking for you, should go on to give a surgeon a pecuniary interest in cutting off your leg, is enough to make one despair of political humanity. But that is precisely what we have done. . . . Scandalized voices murmur that these operations are necessary. They may be. It may also be necessary to hang a man or pull down a house. But we take good care not to make the hangman and the housebreaker the judges of that. If we did, no man's neck would be safe and no man's house stable."

The idea of State medicine is of necessity a modern one, bred of democratic thought and a revolutionized theory of medicine. It could not take root in a state of society that placed little value on individual life, and wherein so-called medicine was based on superstition and empiricism. Chief factors in hastening its recent growth have been the establishment of the germ causation of disease, which has vastly widened medicine's field of usefulness; enlarged trade relations, following the introduction of improved transportation facilities, which have demanded protection from interruptions due to epidemic disease; and poverty, born of an era of industrial exploitation, which has compelled governments and municipalities to recognize the necessity of State industrial insurance and medical school inspection.

Already the larger part of the field of preventive medicine is administered by the State. Our

public health services are salaried bodies. In the regulation of quarantine, abatement of nuisances, education of the people out of their sanitary vices, it is a necessity that only those physicians who devote their entire time thereto, and are independent of the good will and fees of the public, can give effective service. It is obvious that a privately feed profession can accomplish little toward abating occupational disease due to the ignorance and greed of employers; or the ravages of social disease, so long as the idea of professional secrecy be upheld; or nutritional disease by control of the purity of foods so long as it is opposed by the financial interests of manufacturers. The abrogation of these diseases is an ideal possible of near fulfilment, and leaves little to the future therapeutist in this field, although few would limit his field to the single function suggested by Sir Almroth Wright in declaring him to be merely an immunizer.

Another field of medicine in which it is apparent that no physician can work effectively save one who has no pecuniary interest in his patient and is free to tell the truth, is that of imaginary disease. This is the harvest field of every irrational form of healing. It has been said that the faith healer is the only practitioner who can tell the patient there is nothing the matter with him and charge him for it; and, I may add, continue to do so indefinitely.

The practice of the laboratory medical sciences is already relinquished in theory to State administration. Indeed, there is a general demand from the profession for State and municipal laboratories with salaried directors with time and equipment at their command that is impossible to the physician in private practice.

There remains but a narrow field of clinical medicine, surgery, and obstetrics in which it is still necessary to establish the principle of State medicine.

The ideal of medical administration must be to bring as nearly all persons as possible under medical supervision; to establish a higher quality of professional ability and a more effective application of that ability. The number of persons who feel an unjustified dread of the doctor's fee, either because ignorant or actually unable to pay it, and who, therefore, fail to avail themselves of medical supervision, is large; and the number is increasing because of economic causes. Medical school inspection aims to counteract the effect of this tendency. Large industrial establishments are already introducing salaried medical service. Such innovations pave the way for the ready acceptance of State medicine in its entirety. Instruction in school as to the fundamental facts in the causation, prevention, and cure of diseases must lead the public increasingly to appreciate and avail themselves of medical care. It may be objected that it is unjust to force medical supervision upon persons denying, on religious grounds, the existence of disease; but, in reply, it may be confidently predicted that when the patient shall have ceased to be a source of money profit to the medical examiner, an early and honest professional opinion will convert to health and sanity most persons who would now resort to irrational forms of healing.

Under State medicine a higher type of physician will be evolved. Economic forces will inevitably operate to lessen the number of medical colleges. State schools will maintain higher standards for entrance and graduation, instead of sacrificing them for tuition fees and the réclame of numbers; and they will command better equipment than is possible to a privately endowed college. A salaried profession will attract a higher type of man and woman—not the commercial, whose aim is ever to exploit the public, but that which seeks to render service to society; men and women attracted by the scientific aspect of medicine, who desire only a sure income sufficient for their reasonable demands, and freedom from the financial uncertainties and personal irritations of competitive practice.

Under State medicine effective professional regulation will be possible. In the interests of public safety our railroads, probably our best examples of industrial organization and management, already subject their employees to physical tests, require temperate habits, and insist generally upon honesty in business dealings. Is it less necessary for the State to subject to efficiency tests physicians, who assume responsibility for human lives—tests as to acuteness and accuracy of sense perception, quickness of response, resourcefulness, endurance; to require temperate habits and, in all things, honesty? Professional and personal morals are inseparable, medical legend to the contrary notwithstanding. Again, railroads recognize the fallibility of the normal human mind, especially when subjected to strain, or when, through long practice, performing its duties automatically. The safety of the train is not entrusted to the individual, but he is hedged about by various mechanical checks. Is the physician to be the sole arbiter over life? Is the patient to be vouchsafed no safeguards? The conscientious physician must join the public in making his answer to this question a most emphatic negative.

As at present conducted, consultations are generally ineffective, and too often are also open to the charge of a recent laywriter of being "a conspiracy to hide shortcomings." They are regarded by the laity, not as necessary to the conduct of every case (which they really are), but as a confession by the physician of his own weakness, or his lack of hope for the patient's recovery. The choice of consultants is determined by the unfounded personal predilections of the patient or his family, or by the selfish interests of the physician. The ideal consultant is that exceptional physician who is neither too insistent upon details nor tolerant of violations of principle; who possesses wide experience and a judicial mind; who has an eye single to the welfare of the patient; who is subject to no temptation either to condone mistakes or to omit acknowledgment of merit. Such a consultant is impossible under a competitive system. Under State medicine there could be created in every community a staff of official consultants, required to be called upon not singly but in twos or threes, to pass upon every mooted operation and every case of critical illness.

Such consultation would in fact fortify the attending physician and safeguard the patient, as the present system does not and can not. Under a system of State medicine, applying legal tests and penalties, the aim of defense of a physician charged with malpractice would not be the acquittal of the defendant, guilty or not guilty,—thus lessening the liability of all physicians—but rather the determination of individual innocence or guilt, efficiency or inefficiency. It may be predicted that conviction would mean revocation of one's license, and not—as at present—a brief term in prison, or an absurdly small fine, with opportunity thereafter to repeat

the offense. Malpractice would be reduced to a minimum.

Under State medicine professional ability could be vastly more effectively applied. Assignment would be possible to that particular field of practice for which talents and temperament might fit one; and the physician would not be compelled, as at present, in order to eke out his income, to undertake much of which he is incapable. Discrimination would not obtain, as now against the highest professional type—the scholarly, unassuming, conscientious, and frank physician. Women physicians would come naturally into exclusive occupation of those fields for which age-long experience and considerations of mortality and ethics fit them. Equalization of professional burdens would be possible by sending physicians out in rotation. There would no longer exist the two classes of those physicians who do and those who do not perform charitable social service.

State medicine promises vast economic gains through narrowing the limits of disease and accident by increased and closer cooperation between profession and public, in an untrammeled devotion to preventive medicine; through abrogation of unnecessary operations and visits, and attendance upon imaginary ills, which are now a source of profit; through concentration in buildings, equipment, and staff, thereby avoiding the useless expense incident to their duplication. What expenditure is made will be devoted more largely to essentials and less to trivial ailments.

It has been objected that remuneration will be less. State medicine will indisputably operate to level incomes in the interests of the profession as a whole. Doubtless there would be an ascending salary scale, based upon the term of service, as in the army. Judged by the precedent of other public services, the result will be the raising of the average professional income, with reduction of the absurdly disproportionate incomes of specialists and surgeons.

The obstetrician, guiding through the perils of pregnancy and labor a hundred mothers, performs services of as great value to the State as he who performs a hundred major (albeit necessary) operations, or he who corrects a hundred defects of vision. That some professional incomes should be so disproportionate to the value of the service really rendered is indefensible.

Again, it is objected that under State medicine the individual's choice of his physician would be impossible. This objection is sufficiently answered by the unwillingness of any individual to credit another's wisdom in choosing any other physician than his own. A State medical service would hardly interest itself in supplying charm and entertainment along with medical service, but would be solicitous solely for the effectiveness of such service. Undoubtedly gross defects in manners or personality would force their possessor into some department of medical service where personal contact between patient and physician did not obtain.

Again, the fear has been expressed that State medicine would destroy professional ambition and individual development by removing the possibility of large pecuniary profits that are a spur to ambition under the present system. Those who express this fear overlook the fact that physicians at present do not compete, but appropriate. In fact, the close association in the work of State-employed physicians and stricter accountability for results than at present obtains, would act as the most powerful incentive to do one's best.

It has been objected that a State medical service is impractical. Facts thus far accumulated support a contrary conclusion.

While admittedly not above criticism, our National Public Health Service has proven strikingly practical and effective in its workings. Witness the sanitary reclamation of Cuba, Panama, and Manila, and the stamping out of bubonic plague on the Pacific coast. Our municipal public health services, though sadly handicapped for lack of funds, achieve results far greater than were possible of accomplishment by a privately feed profession. Medical school inspection is the most practical conceivable method of bringing society under medical supervision. It is simple and economical in operation, and wherever fully carried out—as it is especially in our largest cities—it has given results of incalculable value. In the last few months, the quasi-partnership between the British government and the British medical profession, in the operation of the Medical Insurance Act—the most striking and revolutionary piece of recent legislation respecting medical practice—has demonstrated the need and efficacy of State medicine in its entirety. This necessity has been recognized and voiced by many of the leading British physicians.

True, the Act involves the inherent weakness of responsibility divided among duplicated boards and committees; it is not national in scope, since women and children do not fall within its provisions; it admits physicians indiscriminately to the panel; and it makes no provision for consultations. Yet, despite all these imperfections, the Act has redounded greatly to the benefit of the British people and the profession. Although at first bitterly opposed by the British medical profession on the grounds of its providing for contract practice, 87½ per cent. of the profession are now registered upon the panel —20,000 out of 22,500 in general practice. Since the act has gone into operation, for one-third of the population $1,150 apiece has been paid by the government to the physicians on the panel—which means, if the remainder of the population pay in like proportion for medical service, as they indisputably do, an increase of from $750 to $2,000 in professional income. The fees paid to assistants have been increased from $10 to $15 to $29 and $40.

While 7,000,000 workers were assured free medical attendance under the Friendly Societies, now, under government insurance, 14,000,000 enjoy that benefit. Professional opposition now comes from the few not on the panel—some 5,000 organized as the Medical Guild; and even they admit that a majority of the profession, politicians, insurance companies, and the general public support the Act. What greater proof could there be of its efficacy? I quote a leading English physician:

"I believe that they (the critics of the Act) could only come to the same conclusions as I do—that the general practitioners, who are the vast majority as well as the backbone of the profession, have gained under the final conditions of the insurance act what amounts to an emancipation."

With municipal salaries substituted for private fees, the Mayo Clinic at Rochester, with its perfect system, specialized staff, adequate equipment, constant professional association and consultation, would furnish a fit model for what the medical organization should be in every community.

SPINAL SUBLUXATIONS; THEIR NATURE AND CAUSE.

By JAY H. RADLEY, M.D.,

NEW YORK.

For not less than sixty years, and possibly much longer, there has been practised in Bohemia, in the treatment of disease, a method known as Napravit (to fix), consisting of manual thrusts upon the spinal region of the patient. In this country, within the last two decades, have arisen, and grown to considerable proportions, at least two sects of practitioners whose therapeutic resources are manipulations addressed principally to the vertebræ, their efforts being directed mainly to the correction, or removal, of spinal lesions, or subluxations—the ribs and other bones, however, receiving some attention also.

Jennerian vaccination, though championed by a member of the regular medical profession, was long denied the recognition which its convincing results finally compelled. Diphtheria antitoxin, given to the world by one of undisputed scientific attainments, was pooh-poohed, derided and condemned for years, in face of its demonstrated efficacy in saving life and preventing disease.

It is hardly surprising, then, when a new idea as to the nature and treatment of disease was promulgated by irregular, unrecognized and contraband practitioners, that they, their theories, and their practices should be scouted, derided, denounced, and declared unworthy of consideration, even, much less open-minded investigation. But when, as in the previously mentioned instances, indisputably favorable results, in large numbers, attend these practices, is it not at least permissible to make some inquiry into the merits of the question?

To mention but a single instance that might be multiplied by those more familiar with the history of therapeutic progress, we may recall that the medicinal properties of Peruvian bark were known and utilized by those outside of the medical profession for some time before their adoption by the doctors. Is it any more impossible now than then that something else of real therapeutic value may, possibly, come from outside the fold?

Aviation and wireless telegraphy are facts of almost daily experience to a limited number of persons—and even to-day wireless telephony is being reported in the newspapers. The probability that vastly more people have not witnessed these practices than have, is no evidence at all that they are myths or delusions—they are demonstrable facts to any one who will permit himself to be shown; the principles and forces upon which these practices depend have always existed—their discovery, application, and utilization only being modern.

The possibility that not a single medical man has ever palpated a spinal subluxation or witnessed its correction and the results thereof, is no proof at all that such a condition does not exist. One convincing, positive demonstration outweighs in evidential value all the speculative, yes, scientific, negation that can be accumulated.

In literature reaching the hands of the recognized medical profession, there is such a scarcity as to amount almost to absence, of matter dealing with spinal subluxations; and of that which comes to their notice, practically all of it is so misinforming and misleading as fully to account for the almost universal denial, by physicians, of the possible existence of such a condition. These facts furnish the excuse for this paper.

With possibly a single exception practically all of the existent literature dealing with spinal subluxations indicates that they who have made most of, and written most about, these lesions have an absolutely erroneous notion of the lesions—that they conceive a subluxation to be what it is not and can not be; and when such matter reaches the eye of a physician who is familiar with the structure and functions of the body, he most promptly and naturally discredits the whole theory and every deduction drawn therefrom—the facts being that a very real condition has been presented in language descriptive of an impossible condition.

Nearly all the literature of spinal subluxation describes it, or at least gives the conception of it, as a condition in which a vertebra is shifted from a fixed normal to an equally fixed abnormal position —comparable, for instance, to a protruding, indented, rotated, or inclined brick in the solid wall of which it is a part; such an impossible condition is, of course, not a subluxation at all.

The spine is an articulated column of bones; between each pair of vertebræ a limited range of motion in every direction is possible; the column as a whole, when the body is erect, is capable of flexion, to a greater or lesser extent, in every point of the compass, and also of rotation about a vertical axis.

In studying the relations of the various vertebræ with their adjacent neighbors, it is well to arrive at some fixed point from which to start, and in locating such a point it seems desirable to define what I have chosen to term a "standard pose." In defining this standard pose we may be guided by Cunningham's "Anatomy," wherein, for purposes of accurate description, the body is supposed to be standing upright, the heels together, arms hanging by the sides, palms looking forward, thumbs pointing laterally, the head erect upon the shoulders, and the face directed forward, thus bringing the external auditory meati approximately in the coronal plane which would cut the astragalo-tibial articulations.

Studying, now, an individual who has assumed this "standard pose," and in whose spine no subluxation exists, we may select any point indifferently—let us say, for instance, the seventh dorsal vertebra. If, now, the body be put through various movements—flexion, extension, lateral flexion, rotation—the sixth dorsal vertebra will, with reference to the seventh, describe certain movements and, in any other pose than our "standard," assume a position of rest with reference to its neighbor below, different from that relative position when the body is in standard pose.

But if, with the body in standard pose, the relation of the sixth and seventh vertebræ be such as it *should* be with the body differently posed—as, for instance, with the trunk flexed laterally—there exists a subluxation of the sixth. (It seems preferable to speak of the upper vertebra as the subluxated bone, in the same way that we would speak of a house being displaced upon its foundation, rather than the reverse.) And likewise, if, when the shoulders are rotated to the left, the sixth vertebra comes to such a position of rest with reference to the seventh as it *should* occupy when the body is in standard pose, a subluxation exists.

The sixth dorsal vertebra, poised upon the seventh, through the articulation, has a field or sphere of motion; it may incline forward, backward, laterally, or in any angular direction, or it may rotate. There must, then, be for it a center of motion

which would be located at the intersection of the vertical, transverse, and anteroposterior axes of motion. When subluxation exists this center of motion is abnormally situated; with the body in standard pose, this center is where it should be in some other pose; and in any pose this center is where it should be in some different pose—possibly a right lateral flexion of the trunk bringing the center where it should be when the trunk is flexed to the left.

To get a clearer idea of this displacement of the center of motion let us compare this sixth dorsal vertebra with a loaded ship. Laden with such a cargo as it is designed and adapted to carry, and that cargo being properly disposed in the ship, the vessel will float, in perfectly calm water, vertically; and it will have a center of motion about which it will pitch and roll when in rough water.

But let the cargo be lightened or increased, or shifted forward or aft or laterally, and the center of motion will be correspondingly shifted. The vessel will still pitch and roll in rough seas, while in still water it will float at rest higher, lower, tilted, or listed, as the case may be. At no time, however, in calm or in tempest, will the vessel at any designated moment occupy the same position that it would occupy, under like conditions of water and wind, were the ship's center of motion in its normal location. The vessel will still be capable of motion in every direction, but the range of that motion will be changed or restricted in certain directions.

A subluxated vertebra is not one fixed in any one abnormal position, but is still a movable segment of a flexible and movable column, whose field or sphere of motion has shifted from normal and whose range of motion may or may not be restricted in certain directions; naturally, too, its various positions of rest are also changed, so that it will come to rest, with the body in standard pose, where it should rest with the body in some other pose.

That spinal subluxations are of frequent occurrence; that they attend, if they do not precede and cause, disease in remote tissues; and that correction of these lesions is followed by a restoration to normal condition and function of such remote tissues (at least subjectively to the patient, as evidenced by the disappearance of symptoms), are all matters of repeatedly demonstrated fact, though the exact pathology of the lesion may yet be a matter of dispute—but then, quinine was largely and successfully used in the treatment of the intermittent fevers for a long time before we made the acquaintance of the *Plasmodium malariæ*.

The vertebræ are connected by the anterior common, the posterior common, intertransverse, interspinous, supraspinous, and capsular ligaments, the ligamentum subflava, and the fibrocartilaginous intervertebral disks. While the proposition may be difficult of positive proof it seems probable that some undue contraction or relaxation of some of these fibrous tissues is responsible for vertebral subluxation. But then, how account for the faulty contraction or relaxation? Mainly, they are the results of traumatisms.

Who has not had falls, strains, wrenches, blows upon the ribs, or other mishaps—possibly too trivial to attract much attention at the time, and soon forgotten—which may have been followed by either one of two results: certain ligamentous tissues may have been just sufficiently overtensed to stimulate them to excessive contraction; or, such overtension may have been so extreme as to suspend reactive capacity, depress tone and contractile power, and leave an abnormally relaxed condition of the injured tissues; either of which conditions would favor and permit abnormal relations between the connected bones—subluxation.

Still other spinal subluxations are reflex in origin. An afferent nerve fiber transmits centrally an impression, as, for example, when a draught of cold air strikes the back. In the reflex centers of the spinal cord this is reflected to an afferent fiber, whose function is motor, and there follows muscular, ligamentous, or other fibrous-tissue contraction with the production of subluxation and its attendant foraminal change. From now on, even though the primary peripheral stimulus has ceased to be operative, the subluxation acts as its own perpetuating agent, through this vicious circle: First, contraction; second, subluxation; third, foraminal alteration; fourth, afferent nerve irritation; fifth, spinal cord reflection; sixth, efferent motor impulse, and back again to the first factor, contraction. Breaking this vicious circle in any of its arcs, by any means, interrupts the sequence of cause and effect and tends to permit a return to normal conditions.

THE ORGANISM OF SMALLPOX, CHICKENPOX, AND VACCINIA.

By HORACE GREELEY, M.D.,

BROOKLYN, N. Y.

Several years ago it occurred to me that of all the unknown microorganisms causative of human disease that responsible for variola offered the most avenues of possible access: as direct smallpox virus inoculation had formerly been practised with results similar to those following the use of calf virus (vaccinia); as vaccinia virus similar in all effects had been obtained from these animals through the use of smallpox virus; and, especially, as in the vaccine virus we knew that a microorganism must be present whose inoculation into man was frequent and followed by distinct and easily accessible local lesions, thus offering easy demonstration of the specificity of any organism that might be isolated.

With such encouraging thoughts I began, several years ago, to collect material, making fixed preparations from a number of cases of smallpox, to which, through the courtesy of the Kingston Avenue Hospital for Contagious Diseases (Brooklyn) I was allowed access, and, for comparison, similar ones from vaccinia and chickenpox lesions. I also attempted in various ways cultivation from the two latter. Results were entirely negative. So thinking that perhaps after all it was nearly hopeless to expect success with simple methods frequently tried by others of great experience, and having much other exacting work on hand, I put away my slides and threw out my attempted cultures. However, some three months ago having occasion to perform a good many vaccinations, I again made a series of slides and cultures from the vaccinia virus and from the arms of a number of the vaccinated.

The first light that dawned was through the observation that in fluid vaccine virus, by hanging-drop observation, one might frequently see large numbers of motile bodies and that the same, no

matter what vaccine virus was used, could be obtained from the vesicles of the inoculated. It seemed, however, that when attempts to stain were made these bodies vanished, or at least could not be identified, so I resolved to try every staining method in vogue, and any other that possibilities might suggest, in an effort to demonstrate them. It is remarkable how slow and stupid one is when following an unwonted track, and it took me nearly a month, working from seven to twelve nightly, to find that the well-known Giemsa, Neisser, and Unna stains would do the work well. Once recognized it was easy to turn back and discover, on nearly every one of the slides that I had on hand, the same organism. It is hard to discern what one has not previously recognized as an entity!

The organism observed is evidently a sporothrix. In the form of multiplying spores (thus in vaccine virus and in all papules, vesicles, and pustules) it is spherical, its diameter varies in the neighborhood of from 0.3 to 0.6 microns. When actively multiplying all present a nucleus which takes the usual anilin dyes with varying facility. A frequent form is a pneumococcus-like couplet which, when stained by Neisser's method, shows a colorless refractile capsule with slightly pink lining, of figure 8 shape, and, within, a blue-stained nucleus in each section—the two nuclei often connected by a bridge of pink whose intensity varies inversely with the distance between nuclei. When these nuclei are nearest together (cell just dividing) the pink is very intense. In all skin lesions the spores multiply, as stated, developing into branching masses whose units are the same as in the figure 8 shape described. These conglomerations often show, projecting from the extremity of a branch, highly refractile, non-stain-taking spores, borne on the end of a little stem. Several are sometimes seen at the end of the same branch, and often two connected in dumb-bell form. These spores when detached are actively motile, the stem becoming the single flagellum possessed. Muir's or Van Ermengem's flagellum staining method will demonstrate. These spore bodies are evidently the *"Cytoryctes variolæ"* described by Councilman and others. They divide and give rise in skin lesion and in culture to the formations aforementioned.

Under certain cultural conditions (which are being studied and will be reported later) a full mycelial growth develops with hyphæ and terminal spores. This is probably what occurs upon the mucous membranes (nasal for instance) in the beginning of these diseases, and the spores, penetrating into the blood-vessels, are wafted to all parts of the system, landing in the skin capillaries where conditions of lower temperature and more light, perhaps, favor further proliferation. In this connection we should remember how the eruption favors the face and hands.

The organism is gram positive—nucleus purple, capsule sometimes light pink—and when stained with carbol-fuchsin is slightly resistant to decolorization with dilute acid, nucleus resists 10 per cent. acetic well. Organism will not produce a macroscopic growth on any known solid media, aërobically or under hydrogen. Its artificial cultivation is being proceeded with and will be the subject of another paper. It readily passes Berkefeld laboratory filter No. 5. Cultivation has been successful enough to permit the second generation derived from a specimen of the market's vaccine virus to give one take out of two human inoculations. This latter I regard as furnishing proof, according to Koch's postulates, of the organism's specificity.

An apparently identical organism has been readily obtained from the vesicles of twenty-five cases of successful vaccination, from a like number of cases of undoubted chickenpox, and from five cases of recognized and unquestionable smallpox.

Since cowpox virus protects against smallpox; since smallpox virus inoculation produces cowpox; since this smallpox-cowpox virus is equivalent to spontaneous cowpox virus; since an organism, morphologically the same, can be obtained from both vaccine virus and human vaccine vesicles, and also from the papules and pustules of variola, we may conclude that vaccinia and variola are identical, and can easily explain the difference in their manifestations by the fact that vaccination produces a local and at most a lymphatic infection, usually stopped at the nearest chain of glands, and that it represents the inoculation of an organism directly derived from a different species of animal, and therefore probably of low relative virulence, while smallpox is undoubtedly contracted through the respiratory tract and is due to one derived directly from an animal of like species which, as shown, through spore formation, passes into the blood and is thrown to all corners.

It is known that successful vaccination, cowpox, may precede or follow chickenpox. I vaccinated a child of two years several weeks ago during the height of the eruption which passed off with the usual symptoms and was followed by those usual to a successful cowpox take. But so may cowpox vaccination prove successful in some instances after a recent mild take as I have seen on my own arm, so that this is no proof of a different etiology for the two maladies. Further, although the type of eruption is pleaded as distinguishing them, it must be remembered upon what slight difference cases in adults are determined. The extra delicacy of the skin in the child readily explains why a vesicle forms instead of a papule, and one reason at least why smallpox is so typical in negroes depends upon their extremely thick epidermis which lends itself to the production of papules. Still, although from observation the organisms seem nearly identical, before the diseases can be considered the same, much work remains to be done, some of which I hope to do.

In concluding let me mention that before even believing my own eyes in regard to the organism described above I returned again and again to my slides and cultures, each time fearing that the treasure trove might have disappeared or have turned into an ordinary coccus, for which a careless observer might mistake it, as the gold-pieces that were hoarded by the butcher in the Arabian Night's tale turned into leaves, but this has not yet happened; and the *Sporothrix variolæ* remains a realism.

110 Clinton Street.

Aminoaciduria and Hepatic Insufficiency.—Marcel Labbé and Henri Bith note that as the result of the study of twenty-seven patients affected with various diseases of the liver they have concluded that the exaggerated excretion of amino-acids is the result of anatomical lesions of the liver or functional alterations of its cells. They find, moreover, that the administration of peptone in these cases is an effective means of evoking the excretion of the amino-acids.—*Revue de Médecine.*

ARTIFICIAL PNEUMOTHORAX IN PULMONARY TUBERCULOSIS

JAMES CARSON of Liverpool, after conducting a series of experiments on animals in 1821, suggested the possibility of favorably influencing pulmonary tuberculosis by creating an artificial pneumothorax. This was, we believe, the first recorded mention of such a therapeutic measure, but no practical use was made of the suggestion for more than half a century. In 1882 Forlanini of Pavia, Italy, noticed that intercurrent pneumothorax had resulted in cures in several cases of pulmonary tuberculosis but did not deliberately induce the condition until about ten years later, and in 1894 made his first formal report on the procedure. He was followed in 1898 by Murphy, who elaborated a technique for the production of pneumothorax by the use of nitrogen, and reported encouraging results in five cases. From this time many trials of this method have been made, and especially within the past two or three years the method has been widely adopted. French practitioners, however, have been slow in admitting the value of this procedure and the earlier articles published in that country magnified the dangers and minimized the benefits that might accrue from its use.

In view of this fact, a recent article by Murard and Colbert in the *Journal de Médecine de Bordeaux*, June 14, 1914, is interesting. The authors find that since the technique has improved the method of Forlanini does not give rise to the disconcerting accidents which attended its early use in France, and they regard it as really the most powerful weapon we possess in the fight against the destructive caseous forms of unilateral pulmonary tuberculosis. The ultimate results in the most favorable cases are clinical cures; but they are often compromised by premature cessation of treatment due sometimes to the production of adhesions following pleurisy, sometimes to bad management of the case, this latter being occasioned most frequently by the negligence of the patient, deluded as to his complete cure. According to the authors' statistics, Forlanini's method gives satisfactory and lasting results in 45 per cent. of the cases where there is total pneumothorax, and 35 per cent. where the pneumothorax is partial. It should be noted, however, that the authors combine with the rare cases of absolute cure those in which the continuous maintenance of pneumothorax allows the patient to resume his normal mode of life. The complications may usually be avoided by the employment of elementary precautions, such as pure air, proper hygiene, and dietetic treatment. Unfortunately, that rests more in the hands of the patients than of the doctors. In closing the authors say that, with the perfecting of technique following more complete knowledge of the indications and contraindications, this is one of the therapeutic attempts which will justify itself more and more. It may be regarded as certain, they say, that the pneumothorax *per se* has never done any harm. In all the cases treated by Dumarest at Hauteville, which furnished the material for the report by Murard and Colbert, the patients would have run risks as grave and worse in the course of the spontaneous evolution of the disease. That is perhaps typical of the reports from France at the present time.

In spite of all the work that has been done there remain many questions that are far from satisfactory solution. Some authors agree with Murphy that the earlier the treatment can be instituted the better; while others would reserve the operation for the late stages, with distinct abscess formation, hemoptysis, etc. Practically all agree that nitrogen is the proper agent. Most Americans and most of the workers in this field abroad, even in Germany, prefer the puncture technique of Forlanini and Murphy to that of Brauer, who advocates incision part way through the wall and then the insertion of a blunt cannula. Then again, some would employ the method where there is frank involvement of one side only, while others see no harm in using it in the presence of bilateral conditions; for it is an observed fact that in many cases where both lungs have been impaired and the penumothorax has been induced on the side most affected, improvement has been noted on both. The results obtained by the majority of workers have been encouraging but it is evident that the exact value, the indications, and the limitations of this therapeutic resource still remain obscure, and that the observation of a very large number of cases will be necessary before final judgment can be passed.

THE LAWS OF DEVELOPMENT.

IN the development of the individual there are two markedly different periods, the one extending from the segmentation of the ovum to birth and the other extending from birth to adult age. In the first period the rapidity of development increases regularly, while in the second period the rapidity of development decreases regularly. This difference, which was formulated as a law by Buffon and afterward by Serres and de Blainville, is based on the circumstance that from birth onward the maturing of the various organs to the limits imposed by coordination restricts the amplitude of the histogenetic processes.

M. J. Laumonier in the *Gazette des Hôpitaux*, June 11, 1914, in discussing the significance of the above law, emphasizes the fact that the needs of

coordination determine why the development of the child is irregular as regards its duration and unequal as regards the different parts of the body. It was Paul Godin who showed that the current standards for judging of development by means of tables of height and weight are deceptive, inasmuch as they do not take into account the development of the separate parts of the body.

The law of Serres mentioned above is illustrated by the following: An infant doubles its weight in six months, triples its weight in fifteen months, and quadruples its weight in thirty-six months. In other words the rapidity of increase in weight diminishes with time. The changes in the diameters of the skull, of the body, etc., follow the same law.

But like all laws there are exceptions to this one. Godin showed that at the age of fifteen years in the boy the height in decimeters is equal to the figure for the age in years. Before the age of fifteen the figure for the height exceeds that for the age; while after fifteen the figure for the height is less than the figure for the age. This rule applies, however, only to the period between four and eighteen years.

The law of alternation was also delineated by Godin, as follows: The segments of the body (head, trunk, limbs, etc.) alternate in their growth, the periods of alternation being six months. Thus there is an alternation in the growth of the arm and leg, of the thorax and of the abdomen, of the upper arm and the forearm. This alternation would seem to coincide with the organic balancing formulated by Geoffroy-Saint-Hilaire, and to be determined by the needs of correlation. The energy of growth is apparently inhibited by the accumulation of waste products; the growth of one part of the body slows up while these waste products are eliminated; the growth of another corresponding segment of the body keeps on until its own waste products reach a certain volume. There is thus a rhythm of growth which has a metabolic basis.

There is another important law, derived as a corollary from the preceding, and known as "the law of maxima and minima or the law of phases." Growth does not proceed as an even stream but consists of a succession of spurts which, however, follow a regular order. This law is illustrated by the grand maximum of growth during the first few weeks of life, then a rapidly decreasing progression up to three years, then a slowly decreasing progression up to nine or eleven years according to the sex. From the eleventh to the twelfth year in boys and from the ninth to the tenth year in girls (in France) there is a short period of arrest or stagnation which is the first minimum of growth. This is followed by a second maximum of growth, extending from the thirteenth to the seventeenth year in boys and from the eleventh to the fifteenth year in girls. When puberty has been definitely established the second minimum of growth is reached. These alternations of growth are undoubtedly dependent upon the play of the internal secretions, those of the ovary and testicle being operative during the period of the second maximum.

"The law of dissociation" is applicable to the three dimensions. Godin has shown that the height increases more during the warm months while the reverse is the case with the weight. An exception is found during puberty when the growth in height decreases and the growth in weight increases. Occupation, posture, and exercise may modify to a certain degree the order of development. The influence of sex on growth begins at the period immediately preceding puberty. The girl reaches this climax much earlier than the boy. The latter who attains his second maximum a little later than the girl, nevertheless outstrips the weaker sex. Following the twenty-fifth year it is rare for the male to increase in stature, whereas the female up to the age of thirty or even beyond may under the influence of pregnancy add one or even two centimeters to her height.

In the rhythmic ebb and flow of the tides of growth there are numerous variations caused by heredity, privation, disease, change of scene from city to country, etc. Heredity exercises the most potent influence. Indeed, Chaillou and Mac Auliffe attributed considerable importance to a "predetermination of the morphological type." Thus the respiratory type is differentiated early and is characterized in the infant by a thorax more greatly developed than normally and by certain irregularities in its configuration. The muscular type of growth develops later, from the fifteenth to the eighteenth year.

The course of growth, therefore, follows definite laws which are, however, markedly influenced by certain external factors. Unfortunately the stresses of modern life, chiefly the stimulating and enervating environment of the cities, interfere in many instances with natural development. The alert physician to whom is entrusted the supervision of the child should be able to discern when the growth of the latter deviates from its natural channel and should be able to suggest the proper corrective hygienic measures.

QUACKS AS FORENSIC MEDICAL EXPERTS.

It was the late Dr. O'Sullivan, we believe, who stated that the possibility of being pitted against an empiric is the greatest dread and deterrent to the qualified medical expert. In Germany it is known that three millions of the people depend for their regular medical service on 5,500 men who are destitute of a general medical education and training. These include practitioners who usurp the titles of nature healer, physical-dietetic practitioner, Kneippist, etc. This number does not include qualified practitioners who have chosen to practice along any desired line, but the latter are few in numbers when compared with the untaught pretenders in the same field.

In the *Münchener medizinische Wochenschrift* for June 23 we find an article by Neustätter on this subject in which the author deals mainly with the blatant, ignorant charlatan, and cites much information in regard to the qualifications and testimony given by these people. But since they are often the sole medical ministers to families their testimony has to be utilized, and with some claim to

expert evidence. The public has sought to standardize the knowledge of all medical practitioners through society propaganda of the usual "medical freedom" type. This is natural because in damage suits and the like the unqualified practitioners' testimony would be revised by the State expert, (who, in turn, could hardly speak with authority on such subjects as acupuncture). As a matter of fact practitioners along a certain line of work have been summoned by the State, irrespective of their general qualifications.

The difference in these respects between Germany and the United States is wide. We find no mention in the article in question of the new "pathies," Christian Science, and the like. The Germans show chiefly adherence to old methods which have dropped out of use, and take but mildly to that which is relatively new.

Epidemic Alopecia Areata.

The current teachings of dermatologists hold that alopecia areata is not a contagious disease. The frequent occurrence of more than one case in the same family has been attributed to a hereditary tendency rather than to an infectious element. There have been described epidemics of alopecia areata occurring in institutions and barracks. Sabouraud, however, reports that he has never observed any such epidemics. At any rate the reality of this occurrence cannot be called into question in view of the authenticity of the observations that have been made. The most recent of these is that reported by Haldin Davis in the *British Journal of Dermatology*, June, 1914. From March to June, 1913, there were 174 cases of alopecia areata among 300 girls of an orphanage. Strict measures were adopted: the worst cases were isolated, the heads were washed daily with a lotion of methyl alcohol and soap, and ointments of beta-naphthol and sulphur were applied. The scalps were massaged, in the severer cases a blistering fluid was applied, and in eight instances the scalp was completely shaved. These measures checked the epidemic and by October, 1913, all of the cases had been cured. Although the patches resembled those of ringworm more than those of ordinary alopecia areata, no evidence of any fungus could be found. Microscopic examination of the broken stumps of hairs showed that they were swollen at the free end, not cut sharply across, and within the hair, near the site of fracture, there was an opaque substance, probably of pathological significance, but whose nature is unknown. Davis believes that an infection was the cause of the epidemic, basing this supposition upon the swift spread of the disease and the prompt response to antiparasitic measures.

Simon's Symptom-Complex.

Those of us who object to an eponymic nomenclature of diseases, syndromes, symptom-complexes, types, etc., may as well become resigned to the necessities of the case. Descriptive naturalists have always found such terminology indispensable, and each new species or variety of quadruped, bird, etc., is as likely to be known by its discoverer's name, as by any Latin and Greek descriptive title. This holds good for fungi, bacteria, etc., and also throughout the plant world. At a recent meeting of the Royal Imperial Society of Physicians of Vienna (*Berliner klinische Wochenschrift*, June 29) Erdheim presented a case of "Simon's symptom-complex," which consists in the main of a primary cancer of the female breast, metastases which involve the hypophysis, and consequent polyuria. In the case presented the woman had been subjected several years before to operation for cancer of the breast. Secondary nodules soon appeared in the neck and skin of the thorax. Thirst and polyuria then appeared and persisted for four months, up to the time of writing; these symptoms indicated progressive destruction of the hypophysis. The injection of an hypophysis extract gave temporary relief. Metastasis to the hypophysis may result from other localizations of cancer; but since most of them follow cancer of the breast, the term Simon's symptom-complex (from the original reporter) is deemed suitable, the small size of the metastasis producing no pressure symptoms.

News of the Week.

To Study Feeble-Minded.—A commission to investigate the problem of the feeble-minded in New York State has recently been appointed by Governor Glynn. The commission, the members of which will serve without pay, consists of Mr. Robert W. Hebberd, secretary of the State Board of Charities, chairman; Dr. Max G. Schlapp, director of the New York Clearing House for Mental Defectives, and professor of neuropathology at the Post-Graduate Medical School and Hospital; Dr. Charles Loomis Dana, professor of nervous diseases at the Cornell University Medical School; Prof. Stephen P. Duggan, of the College of the City of New York, and Mrs. Mary C. Dunphy, superintendent of the Children's Hospital, and of the Custodial Asylum and School for Feeble Minded at Randall's Island. A report will be submitted by the Commission before February 15, 1915, with legislative recommendations. It is pointed out that although there are at present about 30,000 feeble-minded persons in New York, accommodation is provided for only 4,000.

Hospital Increases Holdings.—The New York Skin and Cancer Hospital has recently purchased the four-story dwelling at 336 Second Avenue, adjoining the hospital property. The building will be used chiefly for the extension of the dispensary work of the hospital, the upper floor being reserved for dining rooms and accommodations for the employees of the institution.

Child Hygiene.—The Bureau of Child Hygiene of the Department of Health of New York City, which has the supervision of the health of the city's school children, plans to extend the scope of its activities during 1915 and to make its work more efficient. To accomplish this a budget allowance of $554,670, or $123,780 more than this year's budget, will be asked for. The increase will provide nine additional medical inspectors, three surgeons, nine dentists, and eighty-four nurses.

Medical Protest Against a Presidential Pardon.—At a special meeting of the Washington (D. C.) Medical Society on July 23 resolutions were introduced severely criticising President Wilson for commuting the sentence of a physician, son-in-law of a democratic senator, who was convicted recently of misuse of the mails by sending information as to where an abortion could be performed.

The physician, who practised in Washington, was sentenced to two years in prison and fined $500 in the Supreme Court of the District of Columbia. President Wilson, after the Court of Appeals and the United States Supreme Court had sustained the conviction, commuted his sentence to the payment of the fine.

Diagnosis of Cancer.—The Department of Health has issued the following directions for those physicians who desire to have specimens of tissue examined by the State Institute for the Study of Malignant Disease: The specimen should be put at once into ten per cent. formalin in a wide mouthed bottle. A piece the size of a chestnut is sufficient. This should be cut from the suspicious-looking area, viz., where there seems to be a solid mass of tissue, whitish or grayish in color. Avoid the broken-down areas. A section from the edge of the tumor is the best. In flat tumors, as those from the skin, stomach, intestine, etc., the specimen should be cut at right angles to the surface, that the relation of the normal tissue may be preserved. Where metastases are present a portion of these should be included, marked properly or put in a separate bottle. When two pieces from different parts of a growth are placed in one bottle, cut them in different shapes and properly describe them, stating from where each was taken. The specimens should be securely packed to prevent breakage, and information as to the patient's name, age, and sex, and whether married or single, should be supplied, together with the physician's name and address, clinical diagnosis, and a description of the tumor as to duration, size, shape, rapidity of growth, etc.

Hourly Nursing.—The Central Registry maintained by the New York County Registered Nurses' Association announces the establishment of an "Hourly Nursing Service" for those who require the skilled attention of a trained nurse to administer certain necessary parts of the treatment, but who do not need to go to a hospital or to have the constant care of a trained attendant. Inasmuch as the charge is only seventy-five cents per hour, it is certain that this service will meet with a hearty welcome from both physicians and patients.

No "Cancer Houses."—The annual report of the Imperial Cancer Research Fund of London recently issued gives the results of investigations into the popular theory that there exist "cancer houses" or "cancer areas" in which the disease is relatively more frequent. The investigations showed that the theory is without foundation in fact. "Cancer cages" for animals are also declared to be myths. The report states also that experiments and studies made during the year have not revealed any cure other than the early surgical removal of a cancer.

112 Years Old.—Mrs. Emma Waldron of Marion County, Ark., celebrated her 112th birthday recently, 120 of her descendants, including children, grandchildren, great-grandchildren, and great-great-grandchildren, being present. She is the mother of sixteen children, of whom eleven are living, and has in all 723 descendants.

Havana Free From Plague.—Havana was officially declared on July 21 to be free from bubonic plague. No new cases have been reported for several weeks and no infected rats have been found for a long time.

Ambulance Chasers Hit.—The Workmen's Compensation Commission recently adopted a resolution which will do much to abolish the nuisance long known as the "ambulance chaser." The resolution reads: That the commission decline to consider any agreement for compensation for legal services in connection with any claim arising under the law in advance of the performance of the services for which the claim is made; and that in all cases claims for legal services will be considered solely with reference to the actual service rendered upon a statement submitted to the commission upon the conclusion of the service.

Health of Canal Zone.—The report of the Chief Medical Officer of the Isthmian Canal Commission, Dr. Charles F. Mason, shows that during the month of March, 1914, the total number of deaths from all causes among employees was 34, of which 24 were due to disease and 10 to violence, and that during the month of April the total was 27 deaths, disease being responsible for 22 and violence for 5. The annual average death rate per 1,000 for these months was 8.75 and 6.78 respectively; in 1913 the rates were 6.82 for March and 10.29 for April. For the entire population of the cities of Panama and Colon and the Canal Zone the death rate for March was 25.48 and for April 22.33. One case of smallpox was removed from the Pacific Mail steamship Newport on April 16, and recovered. With this exception, no cases of yellow fever, smallpox, or plague, originated on or were brought to the Isthmus during the months of March and April, 1914.

Rutland County (Vt.) Medical Society.—The annual meeting of this society was held at Lake Bomoseen on July 14, when the following officers were elected: *President*, Dr. Edmund M. Pond, Rutland; *Vice-President*, Dr. Charles E. Griffin, Fair Haven; *Secretary-Treasurer*, Dr. Frederick H. Gebhardt, Rutland.

American Roentgen Ray Society.—A meeting of this society will be held in Cleveland at the Hotel Hollenden, on September 9 to 12, 1914. The program promises to be of unusual interest and value. Papers will be read by Dessauer of Frankfort, on the subject of artificial production of gamma rays; by Coolidge, the inventor of the Coolidge tube; by Shearer, and by Duane. The subject of deep therapy and the production of the hard rays will be fully presented and discussed. The rest of the program will be taken up by a large number of papers on general subjects. The medical profession is cordially invited to attend these meetings.

Gifts to Charities.—The Brooklyn Hospital, Brooklyn, N. Y., has received a bequest of $3,792 from the estate of the late Mrs. Jane Benson of that city.

By the will of the late Mrs. Eliza G. Lippincott of Cheltenham, Pa., the sum of $5,000 is bequeathed to the Children's Seashore Home at Atlantic City, N. J., in memory of the testator's husband, Joshua W. Lippincott.

The Methodist Hospital and the Presbyterian Hospital of Philadelphia receive bequests of $5,000 each under the will of the late Samuel Benner of Philadelphia.

The following bequests are contained in the will of the late Jane S. Esternach of Philadelphia: the Woman's Southern Homeopathic Hospital, $19,000; St. Luke's Homeopathic Hospital, $14,000; the Women's Homeopathic Association of Pennsylvania, for its medical, surgical, and maternity hospitals, $5,000; the Philadelphia Home for Incurables, $5,000; the Children's Homeopathic Hospital,

$2,800; the Children's Seashore Home, Atlantic City, $2,800; the Pennsylvania Hospital and Colony Farm, Oakbourne, Pa., $2,800; the Hahnemann Medical College and Hospital, $2,800; the Wills Eye Hospital, $2,800; the Germantown Dispensary and Hospital, $2,800; the Free Hospital for Consumptives, $2,800; the Rush Hospital for Consumption and Allied Diseases, $2,800; the Philadelphia Lying-in Charity and Nurses' Training School, $2,800.

Obituary Notes.—Dr. GRACE PRIOR YANKAUER of this city was killed on July 28 by a fall from a window of her residence. She was born in Middletown, N. Y., in 1874 and was a graduate of the Woman's Medical College of the New York Infirmary in 1898. Dr. Yankauer was an assistant surgeon to Mt. Sinai Dispensary in the Nose, Throat, and Ear Department, and was a member of the Medical Societies of the County and State of New York, of the American Medical Association, of the Women's Medical Society of New York State, of the Women's Medical Association of New York City, and of the Mount Vernon Medical Society. She was the wife of Dr. Sidney Yankauer of this city.

Dr. HENRY A. RICHY of New York, a graduate of the College of Physicians and Surgeons, New York, in 1889, died suddenly while in his office on July 18.

Dr. WILLIAM J. O'BYRNE of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1870, and a member of the Bronx Medical Society, died at his home, from heart disease, on July 19, aged 69 years.

Dr. MICHAEL FRANCIS O'ROURKE of New York, a graduate of the College of Physicians and Surgeons, New York, in 1902, and assistant attending physician to St. Vincent's Hospital, died at his home from pneumonia, after a brief illness, on July 22, aged 36 years.

Dr. HELEN DE WITT JUSTIN, formerly of Belleville, N. J., a graduate of the Woman's Medical College of the New York Infirmary for Women and Children, New York, in 1879, died at Rochester, Minn., on July 19.

Dr. FREDERICK BRADLEY DOWNS, of Bridgeport, Conn., a graduate of the College of Physicians and Surgeons, New York, in 1878, and a member of the American Medical Association and the Connecticut State and Fairfield County Medical Societies, and former president of the Bridgeport Medical Society, died at his home, from diabetes, on July 17, aged 58 years.

Dr. JAMES JERROLD KNOTT of Atlanta, Ga., a graduate of the Atlanta Medical College in 1859, formerly professor of anatomy and clinical surgery in the Middle Georgia Medical College, Griffin, and a member of the Medical Association of Georgia, died at his home on July 12, after a short illness, aged 75 years.

Dr. LEMUEL CONANT GROSVENOR of Taunton, Mass., a graduate of the Cleveland University of Medicine and Surgery, Cleveland, O., in 1864, formerly a practitioner of Chicago, from 1871 to 1872, lecturer on anatomy at the Hahnemann Medical College, Chicago, from 1873 to 1899 professor of sanitary science and obstetrics in the Chicago Homeopathic Medical College, and from 1899 professor of obstetrics in the Hahnemann Medical College, and a member of the American Institute of Homeopathy and the Chicago Academy of Homeopathic Physicians and Surgeons, died at his home on July 16, aged 82 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE CONGRESS SEASON—TUBERCULOSIS—ROYAL SANITARY INSTITUTE—ROYAL INSTITUTE OF PUBLIC HEALTH—INFANT MORTALITY—NEW PHARMACOPOEIA—PANEL FUNDS DEFICIENT.

LONDON, July 17, 1914.

THE conference of the association for preventing tuberculosis was held last week at Leeds. Sir William Younger opened a discussion on the "House in Relation to Tuberculosis." He described some of the evil dens which he had recently examined and which gave him a sense of wonder and despair that they had so long been tolerated. We are, he declared, planting costly sanatoria all over the country while leaving in every district those evil dens where the bacillus is ever producing new crops of victims. The Marquis of Salisbury declared overcrowding as bad for health as for morals, and whatever stood in the way of economic building he would ruthlessly destroy. Sir R. Philip, physician to the Edinburgh Infirmary and Royal Victoria Hospital for Consumptives, said the hope of the future in this matter was the projection of the searchlight into the home. Col. Kyffin-Taylor said however bad the slums were in Scotland, they had them some years ago infinitely worse in Liverpool, and he pressed on the delegates that tinkering was useless and the only thing to do was to sweep them from the earth and make the municipality properly house the occupants who were turned out.

The second discussion came on in the afternoon, opened by Mr. Knaggs, professor of surgery in Leeds University. He attributed much tuberculosis in children to milk and mentioned cases in which he thought surgery should be resorted to. Dr. Gauvain, of the Treloar Cripples' Home, controverted this, saying the time had come when the knife should be dispensed with as absolutely useless in tuberculosis unless to make good defects arising from previous unskilled treatment. In future cure should be aimed at while preserving the part attacked.

The "Causation and Prevention" was the subject of the communication of Mr. Harold J. Styles, who maintained that in Scotland 75 per cent. of surgical tuberculosis was due to infection by milk. Dr. Nathan Raw went further and said 100 per cent. was due to neglecting this cause during the children's milk-drinking life. One of the best works of the health authorities had been the establishment of sterilized milk depots to which thousands of babies every year owed their lives. He was for more legislation, pending which he advised that all milk should be boiled.

At the Royal Sanitary Institute's Congress—the twenty-ninth of the series—Dr. J. Niven, M. O. H. for Manchester, opened the discussion on the Insurance Act, which he thought added to the available resources against tuberculosis, but at present notification was often too late. Moreover, the buildings required are not yet ready to bring all cases into sanatoria. Dr. Young of Chester expressed disappointment that the act had not led to earlier detection of diseases, objected to the somersault legislation of the Chancellor and urged that the million sterling promised should be distributed by those who knew what was most needed. Dr. D. Forbes said there was not money enough to properly

carry out the domicilary treatment and the extra nourishment often went to the patient's family. In Brighton they were about to devote £600 a year to feeding and housing consumptives. Dr. Holroyde, of Chatham, said the public health acts seemed to do everything except compel the occupier to do his duty. Far too much nonsense was talked about the woes of the slum dweller who was, in most instances, utterly undeserving of sentimental utterances of reformers whose one fetish was liberty of the subject. No man ought to be at liberty to live or act in a manner prejudicial to the health, cost, or comfort of others.

Dr. Snell, M. O. H. of Coventry, had a paper on the administrative control of diphtheria. In his city no attempt at isolation was made and the cases were left at home unless tracheotomy was required, just as those of measles or whooping-cough. He produced statistics of eighty large towns, grouped into six classes, according to the degree of isolation. In eight towns with no isolation the rate, per 1,000 of the population, of morbidity, was .76; of mortality, .197. In ten towns where 27.2 per cent. of cases were removed to hospital the rate of attack was 1.10; of mortality, .155. With 40 to 60 per cent. removals, attack rate was 1.17, mortality .125. He disclaimed any position of advocacy, but it was for those who advised wholesale isolation to explain these figures.

Dr. Killick Millard, M. O. H. for Leicester, raised again a question which is generally thought to have been settled long ago, viz., whether unvaccinated persons were a danger to the community. He admitted that if they were attacked by smallpox they suffered more severely than the vaccinated, but said it was the milder cases which spread the disease, for they were unrecognized in the early stage, and this was very likely to be the case when persons who had been vaccinated many years previously were sickening for an attack. Still more would this be probable in the rare case of a person sickening for a second attack who had previously had smallpox. On these considerations Dr. Millard concluded that such mild attacks were more likely to lead to the spread of severe or fatal variola.

The Congress passed a resolution asking for a royal commission on the organization of the National Public Health system, to consider the need of its unification, and the nomination of a health department, with a minister of State to preside.

The Congress of the Royal Institute of Public Health is now in full session at Edinburgh, with a program which comprises sections concerned with State medicine, comparative pathology, child welfare, hygiene (military, naval, colonial, and industrial). Sir H. Littlejohn took the chair at the opening when the president, the Marquis of Linlithgow, delivered the inaugural address. The Lord Provost, and magistrates, and many distinguished delegates attended. It was announced that the council had awarded the medal for conspicuous service in medical administration to Dr. Milne of Manchester, who has devoted time and energy to tuberculosis. The congress will be continued next week.

The Conference on Infant Mortality was the fourth of the series held under the auspices of the National Association for the Prevention of Excessive Mortality. The president of the L. G. B. had promised to preside, but was detained in the House of Commons about the Milk Bill, which he was determined if possible to get through. The Parliamentary Secretary of the Board, Mr. Herbert Lewis, took his place and proved an excellent substitute. He said the results of the campaign undertaken were remarkable, and pointed to the statistics. Had the death rate during the five years 1906-10 equaled that of the ten years 1871-80, nearly 150,000 more children under one year of age would have died than actually did, and more than 400,000 under five years. This multitude, equal to a large city, had been saved in England and Wales alone, and Mr. Lewis claimed a large part of the credit for the four conferences. Dr. Chalmers, M. O. H., Glasgow, then read a paper on "Ante-Natal Hygiene," discussing its relation to still and premature births and to the mortality of the first month of infantile life. The teaching of mothercraft in public schools and special schools for mothers was therefore urged by Drs. J. Campbell and E. Brikhand.

The new British Pharmacopœia will be published in October. The completed draft was submitted on Tuesday to the executive committee of the General Medical Council and it was resolved that advanced copies should be placed in the offices of the Council in London, Edinburgh, and Dublin, on August 10, where they could be inspected.

Further trouble is threatening about the panel system. So unsatisfactory has this hasty bit of legislation proved that already a party proposes to repeal the compulsory provisions and substitute a voluntary scheme. A meeting of panel practitioners has protested against such a change. Another difficulty is a deficiency of the drug fund in thirty insurance districts—in Birmingham amounting to £5,000. Of course the chemists expect the promised amounts to be supplied and the Pharmaceutical Society is appealed to. It has taken steps to represent the case to the government.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

LOW DEATH RATE IN MANILA—THE HUMAN PLAGUE CURVE—MANILA'S WATER SUPPLY—PERSONALS

MANILA, P. I., June 13, 1914.

ANOTHER marked reduction has taken place in the death rate of the city of Manila for the month of May, 1914, the low figure of 18.97 per thousand having been reached. This mortality rate is 3 per thousand lower than the rate for the same month last year and is by far the lowest death rate that has ever been reported in the city of Manila. The rate for May ten years ago was 41.03 per thousand and as there was no epidemic disease present in 1904 during that month the foregoing figures perhaps furnish a fair index of the sanitary improvement which has been brought about in the Philippine Islands.

The past week a notable reduction has taken place in the number of cases of plague and cholera in nearby foreign countries and no further cases of these diseases have been found upon incoming vessels. There has been, however, a very marked increase in the number of plague rats found in the city. There has not only been an increase in the number of plague rats found but an increase in the number of new centers. The foregoing is of considerable interest in view of the fact that a study of the human plague curve for the past ten years shows that in that part of the Orient located on the eastern coast of Asia and nearby islands and

between latitude 5 and 30 the number of plague cases is highest during May and gradually recedes until December is reached. It then gradually goes up again to the high point of May. A number of observers have expressed the belief that this is due to the fact that the conditions for flea breeding are more favorable during the time that the number of plague cases reaches its maximum. For instance, in Java it has been found that the average number of fleas on each rat is higher at the period of the year during which the highest number of plague cases occurs.

An examination of the bacteriological report of the Manila water supply for the month of May shows that there was a decidedly less number of bacteria in the covered reservoir than in the open reservoir. The average daily number of bacteria in the covered reservoir was 196, while in the uncovered reservoir it was 317. There also continues to be a much larger number of bacteria in the water drawn from the city taps than is found in the water of the reservoir proper, the daily average of the former being 1,565, while that of the latter was 317. A thorough flushing of the entire pipe system is now being made with the hope that a substantial reduction in the number of bacteria in the piped water may be brought about.

Dr. Thomas I. Jackson, who has been a medical inspector of the Bureau of Health during the past two years and directly in charge of the anti-plague campaign in the city of Manila, has resigned his position and will return to the United States in the near future.

Dr. A. P. Goff, who has been on an extended leave of absence in the United States, has returned and resumed his position as chief of the San Lazaro Hospital Division of the Bureau of Health.

Dr. David G. Willets, who was formerly a member of the staff of the Bureau of Science, has resigned and is now connected with the Hygienic Laboratory of the United States Public Health Service at Washington.

Dr. Ruskin Lhamon, who has been the assistant professor of anatomy at the College of Medicine and Surgery, University of the Philippines, has resigned and entered the medical service of the United States Navy.

Dr. Harry D. Gibbs, chief chemist and assistant director of the Bureau of Science, has resigned and will sail on June 15 on the United States Transport for San Francisco. He has accepted an appointment as chief of the Eastern Division of the Food and Drugs Laboratories of the United States Department of Agriculture.

Progress of Medical Science.

Boston Medical and Surgical Journal.

July 16, 1914.

1. Addresses, Fiftieth Anniversary of the Boston City Hospital, June 20, 1914. Hon. A. Shuman, Mayor J. M. Curley, D. W. Cheever, J. G. Blake, G. W. Gay, and F. B. Lund.
2. Salpingitis; the Results of Treatment by the Abdominal Approach. C. L. Scudder.
3. Case of Supposed Progeria (Premature Senility) in a Girl of Eight Years. C. W. Rand.
4. Mushroom Poisoning. E. S. Bagnall.
5. An Interesting Case of Diagnosis. B. T. Burley

2. **Salpingitis Treated by the Abdominal Approach.**—C. L. Scudder believes that the expectant treatment of pelvic inflammation originating in the Fallopian tube is very important. By this the author means rest in bed, laxatives, and some form of periodical hot application to the abdominal parietes with frequent, copious hot douches, the ingestion of large quantities of water and a simple diet, and last but not least important, exposure in the open air and sunshine. Following a careful expectant treatment the surgeon will find at operation a much more localized and definite area of infection, practically a residual abscess, than if no expectant treatment has been followed. The advantages of the abdominal route are: The exact location of the disease can be undoubtedly determined. The procedure decided upon in any given instance can be more safely carried out under the eye. Exposure of the involved parts can be more safely made. The adhesions to the small bowels and the rectum can be more carefully dealt with. The exact condition of the pelvic organs can be accurately determined. Even in very ill patients by a very careful technique the abdomen can be safely protected by moist gauze packs from the operative area, so that no new infection will take place. The author has never seen any serious infection of the abdominal wall following this operation. Shock to the individual, under ordinary conditions, is comparatively slight in the abdominal approach to localized infections. The tube left *in situ* does not in a majority of cases become infected subsequently to an operation for the removal of the other tube. An ovary should be left if one tube is left. If both tubes are removed the ovaries should be removed if they are diseased. It is a good thing to leave at least a bit of ovarian tissue, particularly in young individuals. If the removal of the diseased tube necessitates, as it sometimes does, separation of and dissection of adhesions deep in the pelvis, it may be necessary to insert a rubber tissue wick behind the uterus for forty-eight hours or longer. This rubber tissue wick had best have no gauze in it unless there is considerable oozing in the pelvis; if there is considerable oozing then the gause at the end of the wick serves to favor hemostasis.

3. **Progeria.**—C. W. Rand, in reporting a case of this condition in a girl of eight years, states that progeria as defined by Gilford does not occur in normal children. It only affects those who are the subjects of a form of delayed or arrested growth, or, namely, infantilism. True progeria always occurs in youth. The body arrested in its growth becomes prematurely the subject of senile changes. Infantilism and senilism are both present in the same body at the same time. Progerians pass from delayed childhood directly into a premature old age. Little, if anything is known definitely of the pathology underlying progeria. There have been so few cases reported that the condition is seldom recognized as a physiological or pathological entity.

4. **Mushroom Poisoning.**—E. S. Bagnall states that the fungus responsible for most of the fatal poisoning in this country is *Amanita phalloides*. Poisoning by *Amanita muscaria* is also common, but not so apt to be fatal. *Amanita muscaria* demonstrates its presence by the muscarine symptom complex. Atropine forms a perfect physiological antidote for the muscarine. Unfortunately, however, there are other toxins present. Weight for weight, the preparations from the fresh plant are twice as toxic as pure muscarine. *Amanita phalloides* is a pure white fungus growing in damp woods. It has white spores, nearly white top, with perhaps traces of greenish-yellow around the margin. The stem is bulbous at the base, and it has the ring below the pileus. It is most often seen near oak trees. The symptoms come on usually with sudden intense pain in the abdomen after from six to fifteen hours. There are vomiting, intense thirst, and diarrhea, and the victim gradually wastes away, usually dying in

coma in three or four days. Postmortem examination shows ulcers in the intestinal tract, hemorrhage into the serous membranes, and fatty degeneration of the parenchymatous organs, especially the liver and kidney. The mortality is sixty to one hundred per cent. A third of the top of a small plant has killed a child twelve years of age. As regards treatment atropine for the muscarian type is the specific. For the phalloides, nothing but symptomatic treatment is available. Ford endeavored to produce a specific serum from guinea-pigs, but was not able to obtain sufficient potentiality to make its use practical. In the cases cited by the author atropine was contraindicated and its use should not be recommended as a specific for mushroom poisoning in general. Castor oil is the best cathartic as the salines are said to facilitate absorption. The author's cases strongly suggest the presence in the mushrooms of atropine or a similar substance. There is said to be pilz atropin in *Amanita muscaria* in small amounts, but the symptoms in muscaria poisoning develop in one-half to one hour or, at most, three hours. The symptom complex in these cases is more like that of phalloides than of any other group described.

1. Etiology of Metrorrhagia and Menorrhagia.—J. Riddle Goffe states that the uterine hemorrhages occurring at the two extremes of menstrual life, namely, the adolescent period and the preclimacteric period, have been a great puzzle to clinician and pathologist. The one significant feature that exhibits uniform regularity in these cases is the absence of coagulation of the blood. This lack of coagulability is also characteristic of menstrual blood. The idea therefore suggests itself that the cause of this excessive bleeding may be due to this one feature of incoagulability. A. Sturmdorf, accepting the conclusions of Cristea and Denk that the systemic blood remains unchanged during the menstrual period and that menstrual blood has lost its coagulability, concluded that this change must take place in the endometrium. A simple experiment settled definitely the question that the seat of change from coagulability to incoagulability resides in the endometrium. Sturmdorf and succeeding investigators were driven to the conclusion that there must be some inhibiting element generated or evolved in the endometrium. Conradi, in 1902, published the results of experiments in which coagulation inhibiting substances of unknown nature, which he named antithrombins, were generated in the aseptic autolysis of organs. Histologically the bleeding endometrium represents those very conditions recognized as conducive to the generation of both antifibrin and antithrombin. In these cases the routine curettage not only fails to control hemorrhage, but, by lacerating the subendometrial blood vessels, augments the bleeding in proportion to the thoroughness with which the curettage is done. What is the activating motor center that awakens, regulates, and controls this autolytic disintegration of the subemdometrium capillaries? Certain phases in the developmental cycle of the corpus luteum regularly initiate concomitant morphological changes in the endometrium. As a coadjutor in this function, it is quite possible that the thyroid gland has a part to play. These facts taken in connection with the observation that preclimacteric hemorrhage often persists after complete oopherectomy and that cretinism is attended by amenorrhea, point significantly to some form of vicarious biochemical relation between this ductless gland and the ovaries in the initiation of endometrial activity. What then are the practical lessons to be gleaned from this? First one has learned that the curette, except for diagnostic purposes, has no place here. Ergot has no call for its exhibition in these cases, and for the same reason pituitary extract is contraindicated, for muscular uterine contractions are of no avail. The physiological indications are to reduce blood pressure and stimulate the ovaries and thyroid gland, and through them the endometrium, to fuller performance of their functions. From the standpoint of treatment the cases must be divided into two classes, the pubescent and the climacteric. In the latter case the one suspicious etiological factor that must ever be kept in mind and definitely determined for or against, is cancer, In cases of girls or young women the author is satisfied that curettage, ergot, and pituitary extract have no efficacy. Corpus luteum and thyroid extract are indicated.

3. Prevention of Cancer.—A. C. Wood states that cancer appears to have been recognized and to have received its full share of attention ever since medical observations have been recorded. Notwithstanding this accumulated experience, and efforts at early diagnosis and the most thoroughly operations possible, the mortality rate from cancer is steadily increasing. The recent additions to cancer therapy, such as the *x*-rays, radium, and mesothorium, have so far been found to possess but a very limited degree of usefulness. In the present state of knowledge any marked reduction in the death rate from cancer can be brought about only by arresting precancerous stages of cancer.

4. Direct Application of Radium to Neoplasms of the Bladder.—Winfield Ayres has devised an instrument which may be used through the Ayres operating cystoscope, or preferably through the Buerger operating cystoscope. The radium container is held against the tumor under direct observation. This seems better than to deposit a carrier in the bladder and trust to luck that it will remain in proper position for twenty-four to forty-eight hours. It is considered that 300 mgm. hours are necessary to produce any beneficial effect, and the procedure in the case under treatment is to make application for one hour three times a week. One hour's use of radium in the bladder is more irritating than one hour's cystoscopy without radium. To render the patient as comfortable as possible, two ounces of a one per cent. solution of alypin are injected into the bladder one-half hour before the cystoscope is introduced, and during treatment the bladder is kept comfortably full of a one to four hundred solution of the same drug.

5. Valvular Disease in Infancy and Childhood.—R. Abrahams summarizes the treatment of this condition as follows: In acute or subacute endocarditis, one should push the salicylates to their utmost physiological limit. In acute or subacute endocarditis the child should be kept in bed for three or four months. When the lesion becomes chronic, the recurrence of arthritis or tonsillitis may be prevented by proper dress, hygiene, outdoor life, and suitable antiseptic gargles. When compensation is failing, the patient should be put to bed and given digitalis in mitral insufficiency and caffeine sodium benzoate or the tincture

of strophanthus in stenosis. If digitalis is indicated, only large doses, ten to twenty minims to a child eight or ten years old, will benefit the patient. As the symptoms improve, the dose can be reduced, but it must be continued. A larger dose than this should be given in the terminal stages. Digitalis should be given in mitral stenosis, if marked dilatation or auricular fibrillation is present. In case digitalis is not well borne as evidenced by heart block, or thready and irregular pulse, or retching or vomiting, or fainting spells, then resort should be had to the tincture of strophanthus in half the dose of the tincture of digitalis. Every patient taking digitalis should be given calomel, at least one grain twice a week. Chronic valvular disease demands the continuous administration of iron, which in general is more important than digitalis.

2. The Absorption of Suprarenal Extract from the Nasal Submucosa.—J. D. Pilcher has performed a series of experiments which show that the submucosa of the nasal passages forms an excellent absorbing surface, at least for suprarenal abstract, and probably therefore for other drugs. The effects often approach and sometimes parallel those produced by rapid intravenous injections. Evidently this phenomenon is a result of the very great vascularity of the region, the injected material at times passing directly into the venous circulation. The administration of suprarenal extract in this manner clinically can possibly be of serious moment. In persons in whom a sudden rise in blood-pressure is especially contraindicated, in those with cardiovascular disease, arteriosclerosis, etc., the application of suprarenal extract to the nasal submucosa could well be of serious moment. While the danger of the administration of suprarenal extract to persons with arteriosclerosis should be borne in mind it is also true that arteriosclerosis occurs later in life, when nasal operations are less frequent. In susceptible persons enough suprarenal extract could be absorbed to effect a serious rise in blood-pressure. In conditions of circulatory collapse necessitating rapid stimulation it would seem that the injection of suprarenal extract into the submucosa of the nasal septum or turbinals would be of value. The technique is simple and the quantity of the drug used is readily controlled. This method is not as satisfactory as the intravenous method when the latter is feasible.

3. Hereditary Glaucoma (Simplex).—F. P. Calhoun, in summarizing the reported case of hereditary glaucoma (simplex) concludes that "anticipation" is the most prominent feature. Hereditary glaucoma develops in adults or at an age far remote from the usual period, and whenever a case of glaucoma simplex is recognized in one under the age of thirty, interest should be aroused as to the hereditary tendency. The smallness of the cornea and globe does play an important part; it is not the sole cause, however, for two families of myopes have been reported. Unfortunately few corneas have been measured. General diseases other than gout and rheumatism mentioned by the older writers have small part in the causation of this disease. The liability to transmission by the two sexes is roughly equal. The male sex shows a greater liability to inheritance.

4. Sclerocorneal Trephining for Glaucoma.—W. R. Parker states that the average results obtained from the sclerocorneal trephining operation for relieving glaucoma are better in the noninflammatory type than in the other forms of the disease. The results obtained when the operation was associated with a complete coloboma are better as regards both the frequency of the occurrence of iritis and the effects on the tension than when performed with a partial iridectomy or when the iris is left intact. The remote results may not be as good as those shown immediately after the operation.

5. The Value of Miotics in Chronic Glaucoma.—W. C. Posey notes that the miotics which are best adapted to control intraocular tension are physostigmine (eserine) salicylate and pilocarpine nitrate. This salt of physostigmine is more persistent in its effect and less changeable in solution than the other salts of the drug and is less irritating to the conjunctiva. The author prescribes a solution of pilocarpine to be used about every four hours and one of physostigmine of twice the strength at bedtime, thereby avoiding in a measure the blurring of vision which is occasioned by the action of physostigmine on the ciliary muscle during the day, while the eye receives the greatest effect of the drug during the eight hours or more which elapse between the installations of the drops during the night. In incipient cases of the disease an excellent initial dose is that of one-fifth grain of pilocarpine to the ounce. The strength should be gradually increased so that at the end of a year one grain to the ounce is employed, at the end of the second year two grains, and at the end of the third year three grains to the ounce solution. This strength will suffice to maintain the pupils at the desired point of almost pin-point contraction. Physostigmine should be employed in half the strength of pilocarpine and should be increased in solutions of equal proportions. Conjunctival irritation can usually be avoided by employing only fresh and sterile solutions of the miotics and by frequent cleansing of the conjunctiva by boracic acid solution. Should such irritation arise local applications of argyrol and flushing of the conjunctiva with mild lotions, conjoined with the use of ice compresses and a weakened dose of the miotic, will usually occasion its prompt disappearance.

8. Pineal Gland.—C. P. McCord concludes from his experiments that some of the changes generally attributed to deficiency of pineal secretion may be produced by supplying an added amount of pineal substance. In an effort to reduce to rationality the identical findings derived from two opposing sources the so-called destructive neoplasms of the pineal gland on the one hand and the feeding of the gland on the other there arise two possibilities: First, this syndrome may appear from disrupting the general endocrinous balance from either increasing or decreasing the amount of pineal secretion available for the body's use; second, the cells of the neoplasms involving the pineal gland may retain some of the metabolic and other functional characteristics of the normal pineal cells from which they were derived, and the peculiar bodily, sexual and mental changes in patients with such tumors are all manifestations of increased rather than of decreased pineal activity. One

of the most frequently occurring lesions of the pineal gland is the adenoma, and there is abundant evidence that at times the cells of an adenoma may functionate after the manner of the cells from which they arise. The administration of minute quantities of pineal tissue from young animals to young animals stimulates the growth of the body, but not beyond the normal limits. There are also indications of mental and sexual precocity.

9. **Intraspinal Administration of Tetanus Antitoxin.**—W. H. Park and M. Nicoll, Jr., state that while tetanus antitoxin has proved most efficacious in the prevention of tetanus its employment as a curative agent has been much less successful. This is chiefly due to its tardy administration, insufficient dosage, and the use of the subcatenous method. A series of experiments proved the superiority of the intraspinal method of administration. The authors have obtained records of four consecutive clinical cases of tetanus in which an intraspinal injection of antitoxin was given and in which recovery ensued.

10. **Vesicovaginal Fistula and Rectovaginal Fistula.**—By H. O. Marcy. (See MEDICAL RECORD, June 27, 1914, page 1191.

11. **The Hecht-Weinberg Reaction as a Control over the Wassermann Reaction.**—R. B. H. Gradwohl states that Leredde and Rubenstein, reporting a parallel series of tests, using both the straight Wassermann technique and a method which utilized the natural amboceptor in unheated human sera (namely, the Hecht-Weinberg test), showed that the latter test developed a positive reaction in 10 per cent. more cases of syphilis than does the Wassermann reaction. Hecht and Weinberg developed a technique that utilized the emboceptor and complement present in practically all sera and refrained from heating the sera by using active or unheated sera. The group of cases in which the amount of natural amboceptor in human sera seems to play a definite rôle in making a Wassermann appear negative and a Hecht-Weinberg positive, comprise the following: Cases of ocular syphilis; cases of visceral syphilis, particularly of the liver and heart; cases of syphilis that have received intensive but inadequate treatment; provocative cases in which one is seeking to revive a Wassermann reaction in suspected cases, and cases of monosypmtomatic tertiaries. In general, in cases of what might be termed "limited" syphilis this modification will be found of great value. The use of the Hecht-Weinberg test as a control over the Wassermann reaction brings to light many cases of occult syphilis about which the clinical diagnosis is often uncertain. The author's rule is to perform both tests, and as a result of this practice he points to a series of 1,000 cases in which the Hecht-Weinberg reaction was positive in 15 per cent. more cases than the Wassermann reaction.

4. A Common Mode of Deferred Death After Tracheotomy for Laryngeal Diphtheria. J. Biernacki.
5. Artificial Pneumothorax; Fundamental Defects in the Accepted Technique of Inducing Pneumothorax and How to Remedy Them. W. P. Morgan.

1. **Causes of Insanity.**—F. W. Mott notes that the discovery of spirochetes in 12 out of 70 brains of general paralytics, has dispelled any doubt as to syphilis being the essential cause of this disease. Of the total admissions to the asylums of the County of London every year about 10 per cent. are general paralytics. The principal causes of mental deficiency may be summed up in the fact that as regards the functions of the organ of mind, "like tends to beget like." Mentally defective children, particularly if more than one occurs in a family are usually the offspring of parents who are imbecile or of low grade mentality. The causes of the psychoses or true insanity in which so far no adequate explanation by morphological changes in the brain exists, fall into two groups: (1) the toxic, and (2) the degenerative (neuropathic), but the two conditions are more often than not combined. The toxic causes are (a) exogenous, and (b) endogenous. The characteristic true alcoholic psychosis regarded by Kraepelin as chronic delirium tremens is not a common class of case in the asylums, although alcoholism plays an important part in the degeneracy of a stock. The neuropathic inheritance and disorders of the functions of the sexual glands play a dominant part in the causation of the true insanities. There is a marked correlation between the age at onset of insanity and the critical periods of sexual life. It is an interesting fact that in certain types of insanity, especially the primary dementia of adolescence, there occur in quite young females a great diminution of ova, signs of absence of maturation of the ova, and marked fibrosis of the gland. The author considers this to be further evidence of anticipation, by which the children of insane parents are affected at a much earlier age than the parents and in a more intense form. Modern social conditions tend to repress or suppress the natural physiological gratification of the sexual passion especially in women. Its suppression is one of the causes of insanity, especially in subjects with the neuropathic taint, for it tends to continued mental depression and the development of an anxiety-neurosis which in its turn leads to a disorder of the vital functions and a disturbance of the biochemical relations of the whole body, causing an autointoxication. Thus a vicious circle may be established by the interaction of a disordered mind and a disordered body. Dementia præcox is evidence in most cases of an ancestral neuropathic taint. Up to the time of puberty the majority of patients affected by dementia præcox have been intelligent individuals and full of promise. There is not a congenital feeblemindedness but some germinal defect, possibly of durability of the sexual glands, which has a profound influence on the function of the brain, causing at first mental disorder and finally dementia.

2. **Treatment of Ankylostoma Anemia.**—H. B. Day and A. R. Ferguson conclude that patients with slight anemia may benefit from hematinics without the expulsion of worms. But no case of decided anemia can be really improved unless the worms are expelled. Recent cases of moderate anemia from ankylostomiasis are cured by expulsion of the worms, Recovery in most chronic cases is very slow unless hematinics are given. Under treatment with vermicides and iron the rise in hemoglobin is a reliable index to the expulsion of the worms provided the marrow be in a condition to respond. The administration of simple forms of iron by mouth is more satisfactory than the use of organic compounds or hypodermic medication. Manganese cannot take the place of iron. After the expulsion of worms in a moderately severe case the recovery from anemia is quicker when arsenic is given as well as iron. In severe cases of ankylostomiasis the administration of arsenic is often essential to recovery. In such cases arsenic given by the mouth may be ineffectual but hypodermic medication generally succeeds. Arsenic by itself is useless. Iron is always essential to recovery from severe ankylostomiasis. Persistent eosinophilia after the complete expulsion of worms may be attributed to the presence of living larvæ in the tissues. Intense and persistent anemia in ankylostomiasis gen-

erally denotes exhaustion and atrophy of the bone marrow.

4. Deferred Death after Tracheotomy for Laryngeal Diphtheria.—J. Biernacki states that after temporarily successful tracheotomy there may be a return of obstruction due to loose membrane in the trachea, an issue not necessarily dangerous. Again a further growth of this membrane in the main air-passages below the tracheal incision may be responsible for secondary obstruction of a serious kind, but antitoxin treatment has materially altered the course of laryngeal diphtheria in this respect. Under present conditions it nearly always happens in cases of deferred death that severe lobular pneumonia develops. Death is usually attributed to the pneumonia but this view requires qualification. In most cases of the kind, if allowed to run their ordinary course, death is more directly the outcome of suffocation by a plug of desiccated mucus and inflammatory discharge located in the neighborhood of the tracheal bifurcation, as is proved by the immediate relief of obstruction and marked general improvement which frequently ensue when the plug is removed with forceps after such cases have become serious or are even moribund.

July 6, 1914.

Hysteroneurasthenia or Chronic Appendicitis?—Rheindorf concludes a serial article on this subject, in which numerous collateral topics are discussed. One refers to the so-called "normal appendix" removed after apparently mistaken diagnosis. The proportion of these is becoming less, as a result of improved microscopic diagnosis. The entrance of round worms in the appendix is able to set up morbid alterations. Some of the slight changes in the appendix, long deemed artefacts by the microscopist have been explained in this manner. Numerous microscopic sections show the oxyuris in relation to the lymph nodes and spaces, in which they are seen to compress the surrounding parts. Their presence in the appendix does not necessarily mean that the patient has ever suffered from seat worms. In regard to women who complain of chronic pain and tenderness over the appendix region these symptoms are certainly nervous in part. It is also true that the condition which gives rise to the nervousness may be the presence of the oxyuris in the appendix. In childhood these worms may do their damage by causing a mild form of afebrile appendicitis. The organ, throughout the resulting kinking, adhesions, fecal calculi, etc., may lead eventually to an infectious appendicitis. This sequence has never yet been demonstrated. The author concludes that vague pains in the appendix region with the latter in seemingly normal condition of the organ means in the vast number of cases that the oxyuris is at fault. In 20 to 30 per cent. of all appendicitis in adults, the organ contained the parasite while in children the percentage is 50. But in acute inflammatory cases it is as low as 12. The importance of the problem has become aggravated by the fact that we know as little about the relationship between parasites and appendicitis as we did twenty-five years ago. This lack of progress ought to lead to a special new research of the problem.

Histological Variations of Fowl Sarcoma Generated by Filtrable Virus.—Peyton Rous claims that still another variety of fowl sarcoma has been isolated. There is nothing about it to prejudice the belief that sarcoma is a true neoplasm. The foci can only be demonstrated after the malignancy of the tumor and the virulence of the agent have been heightened by repeated transplantation. In the new form the sarcoma can be made to develop only in supersensitive hens and under special circumstances. Even then the phenomena are but subordinate in degree of general neoplastic procedure. There is no special morphology, all phases being represented. The other types of fowl tumor which have been cultivated in this laboratories—osteochondrosarcoma and sarcoma with fissural blood vessels—show little resemblance to the new discovery.

Münchener medizinische Wochenschrift.

June 30, 1914.

Caramel Regimen in Diabetes.—Grafe's results from this plan of treatment are as follows: The number of cases treated was 25. Caramel, given in very large doses, hardly increased the amount of sugar in the urine, and this as a rule antagonized the acidosis. If from 100 to 150 gr. per diem are given (up to 15 per cent. of sugar content) excellent results have been obtained in acidosis. That caramel has a high combustion value is shown by the fact that severe diabetics may obtain from 600-800 utilizable calories in this fashion classed under carbohydrates. In regard to the indications for caramel, the state of the digestive organs must be borne in mind. Grape sugar caramel is better borne than the cane sugar form. Should there be any severe enteritis the disease goes from bad to worse but caramel does not aggravate it.

Influence of Sodium Bicarbonate on the Pancreatic Secretion.—Wilbrand emphasizes the fact that this salt appears in the rôle of a panacea for disorders of the digestive apparatus. The laity use it freely for any kind of indigestion, for headache which follows a debauch, etc. This common recognition justifies a research into the mode of action of soda in such conditions. Clinically soda plays a prominent rôle in the treatment of diabetes, and since the latter depends so largely on disease of the pancreas, the author, incited thereto by Cohnheim sought to determine the action of soda on the pancreatic secretion of the dog. A fistula was made which discharged bile and pancreatic juice. Sodium was given by the mouth, with meat; 100 grams of the former, coarsely minced, and 10 gm. sodium bicarbonate. A gastric fistula was also established, and during a period of several hours observations were made at short intervals. Thus during the entire period of observation—in one case for example 4 hours—the dog discharged 666½ c.c. of combined digestive fluids of which 492½ c.c. was gastric juice and bile plus pancreatic juice 72 c.c. It was evident that sodium had reduced the amount of pancreatic juice, and this reduction was the more marked if the soda was given in solution. How may this result be utilized in practice? It is known that bread causes a marked increase in the pancreatic discharge, while the flour of which the bread is made has no such property, also oatmeal, which is nevertheless of efficacy in treating diabetes. These finds suggest a law that substances which are of use in diabetes, do not incite the pancreas to secrete. In this affection absence of pancreatic internal secretion is believed to occur. That the external and internal secretions act independently was until recently the prevalent belief. Cohnheim, however, seems to have demonstrated the contrary. Sodium, oatmeal and other substances which "spare" the pancreas as to its work of external secretion. This sparing may react on the generation of more internal secretion—in other words the said "sparers" are also "hormone-exciters. The essential treatment of diabetes is therefore to spare the pancreas by alkalies, and to revise the diet (meat and milk both excite the gland).

Deutsche medizinische Wochenschrift.

June 25, 1914.

Unusual Calcification of the Arteries.—Magnus-Levy asks if arteries not the seat of arteriosclerosis can undergo a primary calcification. After narrating his case, he asks if lime can be deposited in normal tissues in general, and replies that such an event is possible if there is a saturation of the body fluids with calcium salts. As to why lime is deposited in certain organs as metastases (stomach, lungs, kidneys), this can be traced to the native acidity of the same. In certain tissues the alkalescence as a protective, and other causes must be invoked. In the capillaries lime may be precipitated by slowing of the circulation. In the ordinary sense of the word, lime metastases occur in connection with destructive disease or injuries of the bones. In the absence of the latter we can think of some constitutional anomaly affecting the entire calcium metabolism. We next reach the subject of selective deposition of lime in diseased tissues having a primary disturbance of nutrition. The author's patient showed no general tendency to arterial disease, but she had rheumatic nodules of the hands, representing a mild deposit of lime. He concludes, therefore, that the calcification, present chiefly in the arteries of the extremities, inferior mesenterie, etc., was the result of some mechanical irritation readily explained in folds like the knee and elbow.

Renal Diabetes.—Galambos gives a thorough account of this condition, with conclusions as follows: If with a chronic glycosuria with small or constant amount of sugar we have one or two affections to deal with—viz., ordinary diabetes mellitus with a degree of imperviousness of the kidneys, or a true renal diabetes. If the amount of sugar increases slightly, this points to diabetes, but if it decreases to normal or zero we have to deal with renal diabetes. If the amount of sugar cannot in any way be influenced by diet this speaks for the renal type, while the contrary speaks for simple diabetes. Acidosis occurs in the renal form just as in the latter, and hence diabetic coma can set in unless the acidosis can be controlled by diet, something not expected in renal diabetes, which is in no wise dependent on sugar metabolism. Still the carbohydrates are insufficiently oxidized, as shown by the phloridzin test. The author does not feel warranted in the belief that in any form of diabetes, the renal in particular, there can be a complete absence of the combustion element. We have seen that supposed renal cases end in acidosis, and the diagnosis must be more or less in doubt.

Ehrlich's Side Chain Theory.—Dworetzky of Moscow writes on the hypothetical and in part fictitious elements upon which it is based. It represents only a spun yarn of symbolic auxiliary conceptions. The latter, which comprise it, are individual illustrative pictures. In toto it is an invention, not a discovery; not a hypothesis, but a fiction. Receptors, complements and groups do not exist. Immunity can be understood, yet all of the preceding be ignored. The author, however, gives Ehrlich all the more credit for his results because he has not had the benefit of a real hypothesis, but has called into being something imaginary and made it indispensable as a sort of calculus. Had he had a true theory to work with—one based on many facts—he could not have done work superior to what he has already accomplished.

Deutsche medizinische Wochenschrift.

July 2, 1914.

Hygiene Exposition at Stuttgart, 1914.—Bofinger states that the need of such an exhibition (it was opened May 14) was not apparent to many, because not much time had expired since the Dresden Exposition, it nevertheless became apparent that progress had been made during the interval. The historical section was of much interest, chiefly because in the ages in which medicine was poorly developed sanitation was correspondingly well advanced. Sometimes the most primitive peoples had some sound ideas on sanitation, just as civilized peoples were at times backward in these matters. The popular section treated of the hygiene of home life, with especial reference to nutrition—with especial reference to food units and prices—the hygiene of the mouth, and sexual hygiene—limited largely to plates, models, etc., of patients with venereal disease. In a special section the epidemiology of the great world plague was recommended, tuberculosis constituting a division by itself, while another was composed of the cause and prevention of animal diseases per se and as affecting meat, milk, etc. Water supply, infantile mortality, school hygiene, exercises, abuse of alcohol were considered in succession these bearing largely on hygiene of childhood and youth. Race hygiene, called the youngest child of hygiene, naturally involves breeding, eugenics, mendelism. Its aim is to produce a race which "mendels" on its good side only. In the next group are studied especially the toxic action of useful remedies (salvarsan, etc.). Insurance and arrangements for pilgrimages for the ill form two special branches. Civic hygiene of the military type is seen in arrangements made for handling people after train wrecks. Occupation hygiene affords a wide field of variety, which seeks to illustrate the most opposite conditions—for example anthrox from the sheep and lead poisoning. The hygiene of building construction, and of good milk are compendious subjects. The section on statistics and literary journals and books complete the exposition.

Increase in Amount of Sugar in Blood of Old Diabetics.—Hirschfeld states that the kidneys of the elderly weigh less than those of adults; their secreting component is partly disappeared. The arteriosclerosis natural in these subjects is another component, and the vessels cannot respond readily to vasomotor stimuli. Evidence has recently accumulated which shows that the original conception of an arteriosclerotic nephritis is ill founded. This is practically a malignant process in which the heart is first involved. Despite the numerous attempts by leading students to show that the granular red kidney represents the main lesion, the author asserts that the absence of polyuria (which amounts often to oliguria) with collateral absence of retinal lesions, and of edema (with exclusion of gravity effects) sufficiently exclude the original conception of contracting kidneys, and associates the condition with that of senile nephritis. In diabetes of the aged, therefore, the components which constitute senile involution of the kidney may form a substratum for a special type of the latter. The poorly secreting kidney with its want of lability must be able to dispose of the blood sugar as well as the nitrogen waste. Hence, our notions of renal diabetes may require revision.

Mongolian Blue Spots.—E. A. Cockayne reports the case of an infant aged 11 months of Jewish parentage in whom the blue spots were noticed soon after birth. When first seen, when the child was nine weeks old, the spots were of a clear, slaty-blue color, unaltered by pressure. There were three very large ones on the lower part of the back, one extending into the left gluteal fold, and one on the left flank, two on the right shoulder, and one just below the left deltoid.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

SUBSTANDARD INSURANCE.

SUBSTANDARD insurance includes the consideration of two classes of risks, the difference being simply one of degree. (1) Underaverage risks; those engaged in hazardous occupation, with only fair family history, or with some slight impairment such as poor general appearance. (2) Impaired risks; those with bad family history, with an impaired personal history, or those who have given indication in the past or are actually possessed of some organic disease. A man who is physically impaired is in greater need of insurance than a sound one, and up to a certain point this want can be supplied by some form of substandard policy. Beyond this, the practice is limited by the prohibitive cost. Generally speaking, the sources of increased hazard may be studied under the following four heads: (a) Unfavorable family history; (b) poor general appearance, surroundings, habits, and occupation; (c) previous disease with possible recurrence or with tendency to lead to other disorders; (d) existing disease or lack of vitality. These hazards may be covered by the following methods: (a) Simply increasing the premium, practised by some companies in cases of women applicants, complete deafness, or with certain occupations. (b) Advancing the age; this method is the one commonly followed at present in this country. (c) Placing a lien upon the policy which allows only a stated part of the face value of the policy to be paid if death occurs within a stated period during the earlier policy years, the amount to be paid gradually approaching face value as the policy becomes older. This is by far the most efficient method in cases where the hazard is early. In view of recent laws in certain States, however, which declare that no policy can be issued which provides at any time for the payment of less than the maximum amount in the event of death, the method cannot be followed. (d) The issuance of endowment policies to cover certain slight impairments, especially when the risk is an advancing one. This plan, however, does an injustice to the applicants who desire endowment insurance, as it throws a burden upon the class in the form of risks not good enough for the life plan policies.

No definite description of the rules or principles of any method for substandard insurance can be offered, as there are no settled or universal ideas on the subject. Companies which have written enough substandard insurance to formulate efficient methods, show no desire to impart the results of their hard-learned and expensive lessons to others. Each company has been compelled to depend upon its own individual experience and to start with empirical tables and figures until it reached the point when the substandard business becomes profitable. Furthermore, a company, even when working on a large scale, finds it necessary to continually revise its estimates, lowering the rate on one hand when it is found that too heavy a charge is being imposed on a certain class, or, on the other hand, raising the rate on a certain class when it is discovered that this part of the business is transacted at a loss. A substandard business should be profitable, and, at the same time, fair to policyholders.

In some instances the agency staffs have expressed a decided preference to have their respective companies refrain from transacting life insurance on substandard plans on the theory that the approving officers will be tempted into throwing many border-line risks into the substandard class when, if no such alternative is at hand, a regular contract will be issued. This objection would seem to be warranted if we were to judge by some of the cases in which substandard policies have been offered.

It is impossible, then, to present definite tables and figures upon which a company could begin to undertake the insuring of substandard lives without waiting for their own experience to show the way. The methods and degrees of rating not only vary in the different companies, but it is also found that the ratings in the same company prove inadequate for certain sections of the country, though appropriate for other parts of its territory. General statistics cannot be depended upon for a starting point. Even the tables of the Medico-Actuarial Investigation Committee are often misleading in giving the comparative mortalities. The failure of this far-reaching investigation to give positive and definite results in all its findings is due to the small number of deaths found in some classes, and to the effects of over-selection or under-selection in others.

In order to build up a satisfactory system for insuring impaired risks, the medical and the actuarial departments must act in conjunction for ascertaining the percentage of mortality in the different classes, according to the general and to their individual experience. Having learned the rates of mortality, the actuaries will compile tables from the results which convert the percentages of death rates into the number of years to be added to the age of the applicant, the premium charged being that due for the advanced age. The ratings of these tables should vary with the form of policy. There is a fairly wide difference in rates for life and endowment forms of policies in the younger ages, but as the age advances the difference in the premiums becomes less and less.

In making up a system it will help the actuary but little in determining the premium to be charged if he only has as data the number alive at the beginning of a term of years and the number of the original group living at the end of the period. He must have the deaths year by year. One of the chief factors to be considered is whether the hazard is an early one, such as that belonging to consumptive family histories, or is continuously the same as in occupations, or is an increasing one such as in the case of overweights, rheumatism, gout, or syphilis. The early hazards are difficult to rate properly, for if a sufficient advance of years is added to allow for the early risk, a hardship is created for the later policy years. The Armstrong law is responsible for this difficulty, as prior to its enactment the early hazards were amply provided for by means of a lien upon the contract during the early policy years. In other words, this method allowed substandard insurance to be transacted in the full meaning of the term. If a sufficient number of years is not added to such lives, an injustice is done towards the other policyholders. While consistency cannot be expected to be faithfully observed in all the classes, one thing is imperative—the substandard business must be completely separated on the books from the standard in order to preclude any unfair treatment of the latter and to allow a readjustment of the extra charges to the former.

Book Reviews.

PSYCHANALYSIS. Its Theories and Practical Application. By A. A. BRILL, Ph.B., M.D., Chief of the Clinic of Psychiatry and Clinical Assistant in Neurology, Columbia University Medical School; Chief of the Neurological Department of the Bronx Hospital and Dispensary; formerly Assistant Physician to Central Islip State Hospital and to the Clinic of Psychiatry, Zurich. Second Edition, thoroughly revised. Price $3.00 net. Philadelphia and London: W. B. Saunders Company, 1914.

THIS is a reproduction and exposition of Freud's ideas and a practical application of his theories in the treatment of the neuroses and certain psychoses. It is easy to see that the writer is an enthusiastic follower of and believer in Freud, and he claims that recent psychanalytic literature either confirms Freud's theories or has provoked merely academic discussion and criticism long since, to his mind, satisfactorily answered. We, therefore, browse in a purely Freudian field. The field must be more or less popular. The first edition appeared barely a year and a half ago and was quickly exhausted. The present edition shows some revision, but chiefly enlargement by the addition of new matter. Added matter comprises chiefly discussion on artificial dreams; examples of analyzed dreams; a chapter on the unconscious factors in neuroses; a discussion of "collecting manias," and of pathological homosexuality, and a chapter on fairy tales as a determinant of dreams and neurotic symptoms. Several abstract case histories are interpolated, and a glossary of psychoanalytic and psychosexual terms has been added for the uninitiated.

The reviewer, while acknowledging the many merits of the present publication, asks if the author has not possibly kept too rigidly to the dominant sexual theories of Freud, and in so doing may not have partially neglected to give us an exposition of the evolution of those theories to a broader human experience.

PLAIN RULES FOR THE USE OF TUBERCULIN. By R. ALLAN BENNETT, M.B., London; 48 pages; price $1.00. New York: William Wood & Company, 1914.

IN this little volume of less than fifty pages one finds an excellent exposition of the specific therapy of tuberculosis. The author divides the tuberculins into soluble (T.O.A. and T.O.) and insoluble (T.R. and B.E.) ones, the former containing apparently the metabolic products of the bacilli—the exotoxins, the latter the bacillary bodies themselves—endotoxins. Besides the human source, all these culture products can, of course, also be obtained from bovine sources, and it is interesting to see the author make the statement that it is easier to pursue the treatment of most cases with bovine tuberculin, and this in surgical as well as in pulmonary tuberculosis. The author very strongly opposes the idea that a powerful reaction is not a bad thing and he insists that it should always be avoided by beginning with the smallest possible doses and with necessary intervals. As a whole, the author's views are sound and conservative and the book deserves a careful perusal by all interested in specific therapy.

TRAITEMENT EFFICACE ET PRATIQUE DE LA TUBERCULOSE PULMONAIRE, Par le Dr. J. F. LARRIEU. Price, 2 Francs. Paris: Librairie Vigot Frères, 1914.

THE author of this little book represents the modern school of French phthisiotherapeutists, which is very nearly like that of other countries, with the exception that our French colleagues are much more in favor of medicinal treatment than we care to be in this country. Many prescriptions are given, including the iodides, the bromides, strychnine, quinine, benzoates, turpentines, tannins, and others. Good results are claimed from such medication and some of the prescriptions may be well worth a trial.

RECENT STUDIES OF TUBERCULOSIS; Medical Symposium Series, No. 3. Price, $1.50. St. Louis, Mo.: Interstate Medical Journal, 1914.

THE Interstate Medical Journal has published in a volume the various contributions which appeared in that journal, under its Medical Symposium No. 3. The book is entitled "Recent Studies of Tuberculosis." The volume contains 300 pages of excellent reading matter for any one interested in the tuberculosis problem in its medical, surgical, purely scientific, or social aspect. There are no less than 41 contributors and among them some of the best known authors on the various phases of tuberculosis. Thus, for example, Myer Solis-Cohen writes on Apparent Toxicity of Infinitesimal Doses of Tuberculin; H. Gideon Wells on Chemotherapy of Tuberculosis; Guy Hinsdale on Heliotherapy; John B. Murphy on Pneumothorax; Edward E. Myers on Turtle Tuberculin; Fishberg on Psychic Traits of the Tuberculous; Bucher and Chamberlin on Alcoholic Injection in Laryngeal Tuberculosis: A. C. Jacobson on Tuberculosis and Genius; Mr. John von Pelt, a well-known architect, writes on Open Air Schools and Their Construction. The other contributions are equally interesting but space forbids mentioning them all.

CONFÉRENCES DE RADIUMBIOLOGIE. Faites à l'Université de Gand en 1913 par MM. JACQUES DANNE, PAUL GIRARD, HENRI COUTARD, GASTON DANNE, sous les auspices de MM. JACQUES DANNE, Directeur du Laboratoire de Radioactivité de Gif, et J. de Nobele, Professor à l'Université de Gand. Ouvrage publié par la Société Belge de Radiologie. Price, 6 Francs. Bruxelles: L. Severeyns, Editeur, 1914.

THIS monograph of 148 pages contains an excellent review of the physics and chemistry of radium and other radioactive substances, and the methods of applying them, not only in solid form but also as emanations and solutions. There are in addition illustrations of a number of cases of epithelioma and angioma of the face successfully treated with the various rays emitted by radium. The cases are all of the type which, as is well known, is particularly susceptible to the action of radium. An excellent, classified bibliography of 62 pages is appended to the work. While convenient in form for those who read French, the volume contains but little that is not already known, and omits some important matter which has recently appeared in French and English journals.

OPHTHALMIC SURGERY. A Treatise on Surgical Operations Pertaining to the Eye and Its Appendages, with Chapters on Para-Operative Technic and Management of Instruments by CHARLES H. BEARD, M.D., Fellow of the American College of Surgeons; Surgeon to the Illinois Charitable Eye and Ear Infirmary; Oculist to the Passavant Memorial Hospital, Chicago; Ex-President of the Chicago Ophthalmological Society, Etc. Second Edition. Revised and Enlarged with 9 Plates, Showing 100 Instruments and 374 Other Illustrations. Price, $5. Philadelphia: P. Blakiston's Son & Co., 1914.

THE second edition of Beard's work is excellent. It is a volume of 745 pages, abundantly and well illustrated, and well printed. The first chapter entitled "Para-operative Technic," has to do with dressing, sterilization, anesthesia, bloodletting, etc. A chapter on instruments is followed by chapters on the various parts of the eye and its appendages. The work is the product of a conservative, well-trained mind in a man who has during a long and ample experience had time to carefully weigh and to put a correct value on the different procedures described, and to properly present them. There is much of the personal element in the work, but not more than is warranted by the careful preparation and long experience of the author. Of the works in English on the operative technique of the eye this is certainly one of the best.

TASCHENBUCH DER AUGENHEILKUNDE FUR ÄRZTE UND STUDIERENDE. Von Dr. CURT ADAM Direktor des Kaiserin Friedrich-Hauses für das Ärztliche Fortbildungswesen und Priv.-Doz. für Augenheilkunde an der Universität Berlin. Dritte, vermehrte und verbesserte Auflage. Mit 71 Textabbildungen, 4 fabrigen und 1 schwarzen Tafel. Price, $2. Berlin and Vienna: Urban & Schwarzenberg, 1914.

THE third appearance of this work within six years attests to its popularity with those who are interested in ophthalmology. The volume is one of 395 pages, of convenient size for carrying in the pocket. A feature of the work is the space given to the consideration of syphilis and tuberculosis in eye diseases. The diagnosis and the therapy of these conditions is fully considered. Preventive, curative, and immunitive problems are presented in this work to a fuller degree than in other works on eye diseases of much greater volume. Differential diagnosis is made a feature. A quite extensive formulary found at the end of the book will be welcomed by the beginner. Rules and regulations regarding the requirements of the German army and navy service are included. The work is heartily recommended for students particularly.

THE CLINICS OF JOHN B. MURPHY, M.D. Vol. III, No. 2 (April) Octavo of 213 pages with 55 illustrations. Published Bi-Monthly. Price per year, Paper, $8; Cloth, $12. Philadelphia and London: W. B. Saunders Co., 1914.

IT is almost a Herculean task for anyone, no matter how distinguished as a teacher and operator, to furnish interesting material in the form of clinical lectures addressed to practically the same audience, through publication, for any considerable length of time; and while there is probably no one better qualified than Murphy to put through such an undertaking without soon reaching the stage of repetition and elaboration of inconsequential detail, it has seemed to the reviewer that the last few numbers of the clinics have shown that the task was fast becoming too great even for him. This was foreshadowed to a certain extent in the December number by the printing in considerable detail of a Students' Clinic (for which apology was made in the same issue by the editor), by printing the list of cases operated upon before the Clinical Congress (a matter of somewhat questionable propriety), and by the increasing amount of space that was being allotted to the remarks of visiting confrères. With the present issue, however, Murphy enlarges his field by incorporating the consideration of some of the problems of surgical and general diagnosis. This makes the present number much more interesting and valuable than some of its predecessors; and since the field of surgical diagnosis is large, we may be sure that the clinics will again take on the snap and verve that was so characteristic of the earlier issues. The importation of outside talent is still in evidence, nevertheless, in this issue.

MONOGRAPHS ON BIOCHEMISTRY. NUCLEIC ACIDS. Their Chemical Properties and Physiological Conduct. By WALTER JONES, Ph.D., Professor of Physiological Chemistry in the Johns Hopkins Medical School. Price, $1.10. THE SIMPLER NATURAL BASES. By GEORGE BARGER, M.A., D.Sc. Formerly Fellow of King's College, Cambridge, Professor of Chemistry in the Royal Holloway College, University of London. London, New York, Bombay, and Calcutta: Longmans, Green and Co., 1914. Price, $1.80.

THESE two additions to the series of monographs on biochemistry edited by Drs. Plimmer and Hopkins carry out very fully the idea of the projectors of the plan. This is to provide detached treatises on various departments of biochemistry, each complete in itself and affording a review of all the knowledge available on that particular subject so that as necessity requires a new edition of each monograph may be prepared and the series be kept abreast of the progress made, without the expense of reissuing the whole set as is the case in the large textbooks. The success of the preceding numbers proves the value of the undertaking and the present volumes will be found most useful members of the work. The great amount of investigation that is being carried on in connection with the disorders of metabolism, particularly on gout, gives especial interest to Dr. Jones' summary of what is known concerning the nucleic acids. The introduction comprises an historical survey of the discovery of these bodies and a general description of their properties. Thymus nucleic acid and yeast nucleic acid are then discussed in detail together with their derivatives. The second part of the book on the physiological conduct of nucleic acids is particularly enlightening owing to the endless amount of confusing and often contradictory material that is to be found in the literature. This is all critically winnowed by Dr. Jones and it is shown that many of the discordant results reported have been due to imperfect analytical methods, and also to the use of organs from animals of different species. The accumulated evidence indicates that whereas in the lower animals the end product of purin metabolism is allantoin, in man it is uric acid, and that the human organism does not contain uricase The origin of the urinary uric acid is still open to debate, "but if one is inclined to believe that uric acid is not formed in the body from nucleic acid, he should at least note that the body is equipped with a mechanism that can effect all of the transformations necessary to its formation.

Of no less interest is Dr. Barger's volume on the so-called natural bases, which he defines as substances which are precipitated by phosphotungstic acid. Among these are bodies of such physiological importance as epinephrin, secretin, the active principle of the pituitary gland, and spermin. The list also includes vitamin, the substance which is abstracted from rice when the pericarp is removed in polishing the grain, and the absence of which leads to beri-beri in those who subsist on rice so treated. The terms ptomaine and leucomaine, which are now abandoned, include numerous substances which have been isolated and are separately described. The volume closes with an extensive appendix in which methods for the isolation of the bases are given and their special properties are discussed. Both volumes include comprehensive bibliographies, and may well be termed indispensable for all biochemical workers.

BEDSIDE HEMATOLOGY. An Introduction to the Clinical Study of the So-Called Blood Diseases and of Allied Disorders. By GORDON R. WARD, M.D. (Lond.), Fellow of the Royal Society of Medicine, Medical Society of London, etc. Illustrated. Philadelphia and London; W. B. Saunders Company, 1914. Price, $3.50.

As the title indicates this volume is more especially concerned with the clinical aspects of hematology, the methods of blood examination and the technic of their application receiving very little space. Indeed the chapter devoted to the latter subject is so very brief that it might well have been omitted altogether, for it contains nothing of importance to the practiced worker, while it is altogether inadequate for the needs of the beginner. Judged from the standpoint of the author's purpose, however, the book is an important contribution to the literature of the blood diseases and presents much that is original and interesting. The classification of these disorders has always been unsatisfactory and will remain so until more is known in regard to the etiology of many of them, but the author's grouping is a logical one and affords a practical working scheme. From the clinical standpoint it is perfectly possible to arrange the blood diseases under the headings adopted, viz., generalized and localized affections of the blood forming tissues, affections of red cell formation and destruction, affections of circulating red cells, affections of white cell formation and destruction, and finally, affections of the plasma, and the plan has the merit of simplicity. Many subjects that usually receive scant attention are treated at some length, for example infective methemoglobinemia or microbic cyanosis, and sulphhemoglobinemia. The etiology of the latter condition is still obscure but the author is of the opinion that it is of intestinal origin, probably through the action of some bacterial organism, and suggests for the treatment relief of intestinal stasis, which in some cases may require appendicostomy, ileosigmoidostomy, or even excision of the colon. Pernicious anemia also he regards as a specific infection with an intestinal organism which is possibly a variant of the colon bacillus, though he admits the importance of oral sepsis as producing lesions permitting the additional absorption of bacterial toxins. He considers the disease curable, though the treatment described comprises nothing essentially new. His opinion of transfusion is not very high and he concludes that the only application of this method which rests on a satisfactory theoretical basis is the intravenous administration of very small quantities of red cell suspensions, *e. g.* one c.c. of a 25 per cent. suspension given every three or four days. He is also rather doubtful of the value of benzol in the treatment of leukemia and ascribes greater efficacy to arsenic and the *x*-rays. An occasional slip of the pen may be noted, such for example as the statement that in lymphemia "the virility of male and female patients is not affected." An omission of some importance is the failure to mention the oxidase reaction as an aid in differentiating the acute lymphemias and myelemias. The author still describes the transitional leucocyte as a younger form of the polymorphonuclear neutrophile, though this view has been abandoned by most hematologists. However, as the book presents definite personal opinions founded on clinical observation it deserves the careful consideration of all internists.

CONSIDÉRATIONS BIOLOGIQUES SUR LE CANCER. Par FÉLIX LE DANTEC, Chargé du cours de biologie a la Sorbonne. Price, 1 franc. Paris: A. Poinat, Éditeur, 1914.

IN this interesting little pamphlet there is discussed the biological aspects of cancer from the viewpoint, not of a trained pathologist, but of one whose lifework has been along the lines of general biology. The parasitic and cellular theories of cancer are discussed in a broad fashion. There is but little in the paper which will be of interest to the physician; it is intended rather for the specialist in the field of cancer research.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held May 25, 1914.

THE PRESIDENT, DR. T. PASSMORE BERENS, IN THE CHAIR.

THE evening was devoted to the study of the *Bacillus coli*, which was considered under the following headings:

Cultural Characteristics.—DR. WILLIAM C. THRO said that it was indeed surprising to learn the number of pathological lesions that might be caused by this common bacillus. When injected into small animals death from septicemia usually followed in a short time. Among other lesions might be mentioned peritonitis, pleurisy, meningitis, inflammations of the genitourinary tract, and the bacilli might even be found in the sputum in lobar pneumonia. The colon bacillus had always been of interest to the bacteriologist because of its relation to the typhoid group, but as its occurrence as a disease producer became better known it assumed importance to the surgeon and to the physician. The use of vaccines had also caused its recognition to rise in importance as well as its value as an indicator of the fecal contamination of water. This bacillus was a member of the great group of Gram negative rods, including typhoid, paratyphoid, Friedlander's pneumobacillus, etc. From recent experiments it had been shown that it was very difficult to demonstrate flagellæ in the colon bacillus, more so than in the typhoid organism. When they were present they were fewer in number and shorter than the flagellæ of the typhoid bacillus. The production of indol in Dunham's peptone after forty-eight hours' growth was one of the most valuable characteristics by which it might be separated from the *B. typhosus*. It was also distinguishable from the typhoid organism by a more abundant brownish growth on potato media. One of its most differential characteristics was its great power as a fermenter of lactose in litmus and lactose agar. The carbohydrates had been extensively used in the separation of the typhoid group. By the use of the carbohydrates the colon group itself had been separated into many subgroups. Indeed, it might be that one group was derived from the other. Among the newer differential media might be mentioned that of Conradi and Drigalski, in which the colon colonies appeared red and the typhoid and partyphoid blue. Another of these media was neutral red, in which the colon bacilli produced gas and removed color, or reduced it, while the typhoid and paratyphoid did not behave in this way. In Eudo's media the colon colony was bright red and the typhoid colorless. In McConkey's bile salt lactose the colon bacillus was crimson, while the typhoid was not. Some of the latest work had been along the line of substances that inhibited the growth of the colon bacilli, but allowed the typhoid and paratyphoid to grow, like malachite green and brilliant green. The urine was the most common of the materials sent to the laboratory for examination for the *B. coli*. Such a specimen should be sent in a sterile bottle, and preferably should be obtained by catheter. Usually all the media mentioned were not employed, but they were content with the Gram stain, the presence or absence of motility, the indol test, litmus milk test, and the Conradi and lactose litmus agar tests. From personal experience the essayist felt convinced of the value of vaccine therapy in colon infections of the genitourinary tract.

Bacillus Coli Infections in Infancy and Early Life.—DR. W. MORGAN HARTSHORN read this paper. (Will be published later.)

Colon Bacillus Infections of the Kidney.—DR. HENRY DAWSON FURNISS presented this paper, in which he stated that the colon bacillus was found in such a large majority of renal infections that the finding of other organisms in the culture was regarded as a fault in technique unless the colonies were numerous. The following five questions were propounded and answered: Why were the urinary organs so susceptible to the colon bacillus? Tissues of the body had a certain tolerance or immunity to different infections gained by harboring the infectious organism for shorter or longer times. Again the resistance of certain tissue to certain organisms was inherited. A tissue without this inherited or acquired resistance was very susceptible. Since the origin of man he had probably harbored the colon bacilli in the intestinal tract, but at no time had the urinary organs been the natural habitat of the colon bacillus, and its introduction on such a virgin soil was generally attended with an inflammatory reaction. Furthermore, there were some two hundred strains of colon bacilli and it did not follow that immunity to one strain conferred immunity to all the others. What were the predisposing factors? Conditions causing obstruction with retention and lack of drainage predisposed to infection. Factors lowering the vitality of the body in general and of the urinary tract in particular, such as depressing illnesses, congestions of the kidney from toxemia and exposure to the cold, rendering the kidneys more susceptible to infection. The greater frequency of the infection of the right kidney was probably due to its greater mobility. What were the exciting causes? Among the exciting causes might be mentioned infectious foci, such as furuncles, carbuncles, tonsillitis, abscesses, infected wounds, scarlet fever, whooping-cough, and intestinal diseases, as diarrhea, constipation, Hirschsprung's disease, typhoid, paratyphoid, and appendicitis. Most of these conditions were due to other bacteria, but they paved the way for the colon bacillus. How did it gain entrance? The evidence at present was not sufficient to determine with certainty the method of infection. The preponderance of opinion was in favor of hematogenous infection in the greater number of cases; lymphatic extension in some, and ascending infection in few, if any. In the author's opinion most of the renal infections were due to the breaking up of infected thrombi that found lodgment in the kidney where they developed. The kidney was capable of eliminating many bacteria without being damaged, but factors which caused undue congestion and faulty drainage favored infection. At the meeting last year of the American Medical Association the essayist had reported nine cases of postoperative renal infection, most of which were of colon bacillus origin. A point in favor of these being of hematogenous origin was that pus was seldom found in the urine in the first two or three days of the infection. This seemed to indicate that the renal parenchyma was first infected and the pelvis secondarily. What was the natural course of these infections? There were two classes of cases: 1. Those in whom the onset was gradual and in whon it was almost impossible to determine when the infection took place. 2. Those cases in which the infection was acute. It was essential to determine the infectious organism; patients with colon bacillus infection usually recovered without operation, while the fulminating type due to streptococcus and staphylococcus often demanded a prompt nephrectomy. These cases were usually over their acute symptoms in from five to twelve days. The recovery was complete or they persisted as a pyelitis. Pyelitis cases had exacerbations which were brought on by conditions causing congestions or interference with pelvic drainage. Another type of infection showed ulceration of the tips of the papillæ with no dilatation of the pelvis. This form was actively destructive and not very amenable to palliative treatment. There was still another type in which the kidney was converted into several large pus sacs. Usually patients with this form showed evidences of sepsis and as the diagnosis was usually not made for some time they usually became much run down and emaciated. In treating the acute hematogenous form of the infection the patient was put to bed, given large quantities of water, urotropin, fifteen grains every six hours, and, if the urine was not acid, twenty grains of acid sodium phosphate three times daily, but not while giving the urotropin. The lumbar region was dry-cupped once or twice daily, and an electric pad was applied continuously. A temperature over 102° F. was controlled by alcohol sponging. After the subsidence of the acute symptoms autogenous vaccines were of benefit not only in accelerating recovery, but also in increasing the patient's resistance so that recurrence would be prevented. In the pyelitis cases they attempted to give proper support to the kidney by bandaging and corseting, administered salol or urotropin, gave large quantities of water, injected autogenous vaccines, and built up the general condition. If this did not suffice, the pelvis of the kidney was irrigated with one-half to one per cent. nitrate of silver every five to seven days. At the same time search was made for the primary infecting source, and it was eradicated. The combined functional capacity of the two kidneys was determined and then the relative. For the combined function he used phenolsulphonephthalein; to determine the relative capacity, he used

10 c.c. of a three-tenths of one per cent. solution of indigo carmine intravenously, and then observed the elimination from the two ureters through the cystoscope. If it was determined that one kidney was good and the other functionally greatly damaged, then the damaged kidney had best be removed. For the ulcerative and pus kidney nephrectomy was best, and if this was impossible then drainage should be resorted to. In many cases of arthritis the focus of infection was to be found in colon infection of the kidneys, and treatment of the renal infection would materially affect the joint condition. Their best results with vaccines had been obtained in the cases in which there was an involvement of the renal parenchyma. In the cystitis cases they had been of some value and were a useful adjuvant. Stock vaccines were of little or no benefit, and autogenous vaccines must be used. If the patient was taking urotropin, this might have to be discontinued for twenty-four to forty-eight hours, or the colon bacilli would not grow, even though they might be seen in the urine microscopically.

The Bacillus Coli Infections During Pregnancy and the Puerperium.—Dr. FRANKLIN A. DORMAN read this paper. He stated that the intimate association of the intestinal tract with the generative tract and the interference with the normal mechanics of intestinal action by the growing uterus easily accounted for colon bacilli infections during gestation and the puerperium. Of the various disorders that might be due to this organism he first considered pyelitis. The entrance of the infection in this condition had been variously given as ascending direct, by the lymphatics, or by the blood channels. The pressure of the gravid uterus aided in localizing the lesion as was shown by its occurrence in the great majority of cases in the pelvis of the right kidney, the side to which the womb was usually deflected during the latter months of pregnancy. In the large percentage of pyelitis cases the colon bacillus was the offending organism. The infection usually occurred during the early months of pregnancy. The first recognized symptoms might occur during the puerperium and in such instances one was usually forced to conclude that the condition had had an antepartum existence. The general practitioner and the obstetrician must become more alert to detect this condition. Pyelitis in pregnancy rarely went into infection of the kidney parenchyma. The termination of pregnancy usually favored its cure, but this did not seem to be a necessary therapeutic resort. Active treatment consisted first of postural treatment, the patient being kept in the recumbent position and most of the time on the side away from the infection, with the elevation of the head of the bed. Pain and fever were relieved by an ice-bag to the lumbar region involved. Occasionally a sedative might be necessary. Forced fluids were important in assisting drainage. A diet of buttermilk or pasteurized milk was recommended, and liberal doses of urotropin had seemed of value in diminishing the severity of the bacilli. If the infection persisted autogenous vaccines would be of value. In obstinate cases irrigation was usually curative. An appendicitis coincident with the pregnant state was usually a colon bacilli infection. Of course during pregnancy the suppurative or perforating forms of appendicitis were more dangerous than to the normal patient, the danger increasing the nearer the attack approached labor. An acute appendicitis with onset in the puerperium was apt to be severe. Diagnosis was sometimes masked with other symptoms and the rigidity and location of the tenderness was not so definitely marked. The woman with a chronic appendicitis who was desirous of bearing children had an additional reason for the removal of her appendix. Statistics proved that should she conceive, the chances were greater than ever that the appendix would give her trouble. Temporizing was most dangerous. If pregnancy was advanced the incision should be high, and every effort should be made to avoid the onset of labor. This might be accomplished by the liberal use of opium. In case acute appendicitis was coincident with labor, the safest resort in the presence of pus would be a cesarean section, with Porro operation and pelvic drainage. The statement had been made by De Lee that pregnancy seemed to be a feature of the development of gallstones. In this condition active and severe symptoms might call for operative interference at any time, and A. B. Davis claimed that pregnancy formed no contraindication to the operation. At or near term the uterus might cause difficulty by its position. During labor a distended infected gall-bladder might be confused with or mistaken for puerperal sepsis. Uterine infections of most varied types would not infrequently give evidence of colon bacilli origin or participation. The infection might occur from extrusion of fecal matter during the last stage of labor, associated with vaginal manipulation, or tamponade of the uterus, especially where there had been a tear involving the sphincter. It had seemed to the writer that in some cases the infection was due to infected urine. The colon bacilli might be in association with other pus organisms, and then the virulence seemed to be enhanced. The colon bacillus infection was apt to develop metastases and parametric abscesses were common. Its tendency seemed to be to localize. Prevention was most important in dealing with puerperal infection and this meant care in regard to asepsis and special care if intrauterine manipulation had to be conducted. Examples of divers effects of colon bacillus infection were mentioned as curiosities, such as coincident tubal infections, breast abscesses, colon infections of ovarian cysts, or of degenerative fibroids. There were also authentic cases of navel infection and pyemia of the newborn from the same cause.

Gynecological Conditions Due to the Bacillus Coli.—Dr. WILLIAM E. STUDDIFORD discussed this phase of the subject. As to the frequency of colon bacillus infection, it might be noted that Foskett had reported 34 cases in three years prior to 1914. Ten of these were cases of pyelitis and cystitis without operations, and thirteen puerperal cases, in eleven of which the colon bacillus was found in the urine. In one case they were found in the blood and in another in a cyst of the ovary following hydatid mole infection with the colon bacilli. After three abdominal sections the colon bacilli were found in the urine. Colon bacilli was found in one interposition operation for prolapse in this series and in six cases of pelvic or ovarian abscess. Some of the diagnostic points were abdominal pain, localized to the infected section; a high leucocyte count; a polymorphonuclear count above 80 per cent. and cloudy acid urine which might be confused with the typhoid appearance. Examination of the urine of 139 cases admitted to the hospital since January 1 showed 92 sterile, 28 infected with colon bacilli, 14 with streptococcus, three with staphylococcus, and two with the tubercle bacilli. A plan of treatment that would be an aid in lowering the morbidity from this cause was the giving of high colonic irrigations and urotropin and soda benzoate in large doses for several days before and after abdominal and plastic operations. A buttermilk diet should also be given and iodine should be used in pelvic operations. The essayist concluded that: (1) Infections by the colon bacillus were a distinct condition in gynecological and obstetrical cases. (2) Pyelitis infection might be confused with typhoid fever, appendicitis, salpingitis, or puerperal sepsis. (3) Cultures of urine should be made in all doubtful cases, and in hospital practice every case admitted should have a bacteriological examination of the urine made.

Dr. EDWARD L. KELLOGG discussed this subject from the standpoint of the internist. He said that if he had given this subject more consideration he would have declined to discuss a subject in which the clinician could hope to present little of value, when there were such able pathologists working upon it. It was to the work of Herter that he was particularly indebted for his limited knowledge of this subject. As a gastroenterologist he had found it desirable to consider the *Bacillus coli*, not as a distinct entity, but in connection with the allied or antagonistic bacteria found in the intestinal tract. Without doubt it furnished one of the strongest defenses against the action of the other less desirable inhabitants of the intestinal tract, but apparently it was necessary to keep it in its natural environment if the individual was to be protected against its injurious effects. Turck had shown that this organism might bear an important relation to the production of duodenal ulcer, and in a series of cases which the speaker had conducted during the past two years he had frequently found this organism in the duodenal fluid in cases of duodenal ulcer and gall-bladder infection, although usually absent under other conditions. In combating the activities of the colon bacilli the primary trouble had been intestinal stasis, and this had proven true in several cases of *Bacillus coli* infection of the kidneys that resisted treatment until the stasis was relieved or controlled. All were familiar with the inhibitive action of the *Bacillus coli* in the colon on the activities of such bacteria as the *B. acrogenes capsulatus* and other putrefactive anaerobes. Clinically in the study of cases showing abnormal activity of the

intestinal flora a proper realization of abnormal mechanical conditions in the intestines was essential and the treatment was in large part the relief or control of such mechanical defects.

THE PRACTITIONERS' SOCIETY OF NEW YORK

Two Hundred and Sixty-third Regular Meeting, Held May 1, 1914.

DR. V. P. GIBNEY, IN THE CHAIR.

Cretinism.—Dr. W. GILMAN THOMPSON presented a patient, a cretin, thirty-six years of age. The patient had been born before the days of thyroid extract treatment. Mentally he was not without some development, being able to read his name and write one or two words; attempts had been made to send him to school, but without benefit; the gargoyle physiognomy was noticeable. He did not know anything about his parentage. He had been operated upon several years ago at a hospital and had had sheep's thyroid transplanted into his kidneys. This had resulted in a remarkable group of stones, bilateral, as shown by *x*-ray plates. He had pyuria, but was apparently in fair health. The limbs showed a fair development in proportion to the head. The teeth in the lower jaw were almost horizontal. The boy had had thyroid extract given him when at times he became dull and stupid. Occasional doses of thyroid improved his mental condition somewhat.

Dr. GIBSON said he had seen a case at Coca's clinic in which a piece of thyroid had been put into the spleen and it had worked pretty well. The patient had been about twelve years of age at the time, and at sixteen years she was pretty nearly normal, but she had a large goiter of the spleen. This had assumed the characteristics of a thyroid tumor and she had come in for a splenectomy.

Dr. ABBE asked whether the transplant in Dr. Thompson's case had been made into the pelvis or the parenchyma of the kidney.

Dr. THOMPSON said the transplant was made into the pelvis of the kidneys. There was no other explanation for the quantity of stones.

Case of Hypopituitarism.—Dr. THOMPSON also presented this case. The patient was a young man, twenty-two years old, described by his parents as being "foolish but not dull" as a boy. There was no family history except that in one picture taken with two sisters, one sister exhibited somewhat the same physiognomy. The patient showed a somewhat feminine type of development. Somnolence was extremely noticeable, he would drop off to sleep while standing in the ward. He complained of no symptoms except increasing dimness of vision. The *x*-ray picture was negative as to tumor. He had a marked polyuria. There was considerable toleration for sugar, 200 grams having been taken without glycosuria. He had been getting heavier all the time but lately he had been put on pituitary extract and with the same diet had been losing weight. Whether this was a coincidence or not could not be determined. He had a general furunculosis. The Wassermann reaction was strongly positive. There was an eruption on the chest which might be syphilitic. Sexually he was undeveloped with very little evidence of pubic or axillary hair. The type of obesity was feminine, being marked over shoulders and mammary region. The case corresponded to a case Dr. Cushing had recently noted of hypopituitarism. The patient had a mild stomatitis not due to mercury.

Dr. THACHER said the sella turica looked to him rather small and asked how long the patient had been abnormal.

Dr. CONNER asked what the ophthalmoscopic examination showed and if the patient had any headaches or any epistaxis. He said it was his impression that a good many tumors arising from the pituitary gland were not associated with any enlargement of the sella and might lie almost wholly outside of it.

Dr. THOMPSON said that the patient had been nearly normal four years ago. He was employed as a tailor until one year ago. His somnolence prevented steady employment. He said there was considerable restriction of the field of vision.

Complete Removal of Tongue.—Dr. ROBERT ABBE presented this case, a man who had had the tongue completely removed. At the end of four weeks the man could speak fairly well though somewhat indistinctly. In a short time he would speak much better. With removal of the whole tongue patients could often speak as well as with half the tongue. The patient took all soft food very well and was gaining weight.

Case of Nephrectomy for Tuberculosis.—Dr. ABBE also presented this case, a woman who, seventeen years ago, came to him with tuberculosis of the kidney. She had a bad pyuria and cystitis for two years. The kidney was first drained and later removed. The cystitis was very slow to yield. The bladder was ulcerated and would only hold two ounces. It took several years to gradually become normal. For the last seven or eight years she had had a normal bladder with full retention. The patient appeared in perfect health. There was now no cystitis or tuberculosis; the urine was normal.

Dr. ROPER asked how long the tubercle bacilli remained in the urine after operation.

Dr. ABBE said he had hunted for this in the records of the case but had not been able to find it.

Dr. GIBSON said it was wonderful how long lesions would last when there was a general involvement. He had a patient who had had tubercle bacilli in the urine for fifteen years. The patient had had tuberculosis of the hip in 1889. Dr. Wier operated in the belief that it was a sarcoma. Soon after he developed tuberculosis. The treatment was conservative. He later had an involvement of the testicle; this was operated on and later he had a lesion in the prostate and bladder, lastly the second testicle. The man lived out of town and in good hygienic surroundings and held a good financial position. He had, however, severe incurable genitourinary lesions. Dr. Gibson said he knew a number of people who were going round after nephrectomy and had made apparent recoveries. Lesions in the bladder were apt to get well. You could make a diagnosis by looking at the ureter mouth. The tuberculous material was carried down the ureter. He did not believe treatment of tuberculosis of the bladder was any good. If you treated it it got worse; if it cleared up it would be of itself. He had seen big masses, almost filling the bladder, entirely disappear. Constitutional treatment gave wonderful results with some of these patients. The question of removal of symmetrical organs was a very important one. There was a tendency of the other organ to take up the work. When two kidneys were tuberculous and you took away one you laid a lot of work on the other kidney. Tuberculosis developed very rapidly in the second. If you took out the bad kidney it threw a sudden strain on the healthy one, unless the healthy kidney had already undergone a compensatory hypertrophy. If you took out a testicle in a young man the other testicle would develop tuberculosis, but later in life it was not so likely. It was worth a great deal of consideration. Dr. Gibson said he argued very strongly for the constitutional treatment of tuberculosis. He hoped that in the future there would be no such thing as a surgical tuberculosis.

Dr. BRANNAN said he was recently asked by Dr. J. F. McCarthy what provision there was in the city for taking care of chronic cases of post-operative or non-operative tuberculosis of the genitourinary tract; if none, could not something be done, as, for instance, by using some of the wards of the new Sea View Hospital for such a purpose? There was no provision for the hygienic treatment of surgical tuberculosis as there was for pulmonary tuberculosis. Children were provided for to a certain extent in these cases, but there was no place to send adult patients.

Dr. MEARA said he had recently seen a case who four years ago had had decided symptoms of bladder involvement. This went on two years and was seen by a competent genitourinary specialist who said that both ureteral orifices were involved. The bladder condition was, however, let alone and under hygienic conditions she made great improvement, though still with frequent urination. The question then arose of her marrying. A second examination was made; the kidneys were tested and the right kidney gave good function; the left kidney very little; 25 per cent. of both kidneys were involved. She was advised that she might marry but not bear children. She was advised to have the left kidney removed. She had an operation which showed that two-thirds of the left kidney was a caseous mass, but the parenchyma was not involved. The right kidney showed pyuria. The question was whether the procedure was the right one as against leaving two kidneys considering the improvement which had taken place in the time. The improvement seemed to justify leaving the condition alone.

Dr. ABBE said sometimes there was no question as to the advisability of operation. In his case the patient had a temperature of 103 . Drainage improved that. The patient had to urinate every twenty minutes. In the case of both kidneys being involved it was better to leave the patient to hygienic conditions.

Case of Sigmoid Diverticulitis.—Dr. ABBE presented this case. (See page 190.)

Dr. MEARA said he had had a case of a man whose picture duplicated that shown by Dr. Abbe. Forty-eight hours after a bismuth meal the diverticula had retained the bismuth; 24 hours later there were marked sacculations; after another 24 hours the shadows had disappeared. This showed the necessity for a long series of plates. The case was one of arthritis.

Dr. CONNER said that the evidence furnished by the radiographs seemed to him only to indicate the existence of diverticula and did not prove that the tumor was necessarily due to an inflammation of such a diverticulum, although it seemed very probable that this was the case. It was conceivable at least that the mass might be a carcinoma in spite of the evidence that diverticula existed.

Dr. ABBE said Dr. Connor's point was well taken. He could not tell until section was made that there might not also be carcinomatous change, but the essential fact demonstrated was that there was multiple diverticulitis.

Serum Treatment of Pneumonia.—Dr. J. C. ROPER presented this paper. (See page 187.)

Dr. GIBSON said the question of chills interested him. If you injected anything you could get a chill, such as that following transfusion. Had Dr. Roper tried any control experiments such as injecting normal sera from a normal horse, or immunized sera from human beings? It would be interesting to make such control experiments.

Dr. ROBINSON said that he had not attempted to use serum treatment in private practice. He thought that pneumonia in hospitals and in private practice was a very different thing. In hospital treatment of pneumonia you did not see the patient until the third or fourth day and the conditions for success were bad. Sometimes the patient pulled through, you could not tell why; sometimes they died no matter what you did. He was not impressed with serum treatment. If the cases could be taken care of early enough you got good results with other treatment.

Dr. MEARA said that he had heard the opinion of Dr. Cole that conclusions could only be drawn from a very large number of cases; that it was difficult to get this data together and that an appeal should be made to the boards of hospitals to carry out this method of investigation. The statistics so far were of little value, but if one could indeed drop the mortality 5 or 10 per cent. it was worth while. Dr. Park had spoken at a previous meeting of the amount of immune substance in normal human beings in diphtheria. He said persons who had not had diphtheria had more antibodies than those who had had diphtheria. In normal persons, therefore, there might be sufficient antibodies for the pneumococcus and perhaps transfusion of serum might be protective. This might be investigated.

Dr. CONNER asked if only single injections were given; was there any advantage in repeating the dose if single dosage did not accomplish anything?

Dr. THACHER asked if Dr. Cole had not said that the later results were not as good as the earlier ones.

Dr. THOMPSON asked what type the patients were in the last two charts; were they alcoholic? The serum undoubtedly had an effect of some sort. The investigation should certainly be pursued. The series was too short to draw conclusions. It was important to check results with the bacteriological examination of the sputum. There were variations in organism that undoubtedly caused variations in the results. At Bellevue Dr. Hastings had been treating either with sera or with vaccines; the results were not satisfactory with sera. Dr. Niles had been giving vaccines to the pneumonia cases in the service. The patients did better on vaccine treatment.

Dr. ROPER said in answer to Dr. Gibson that there was no explanation of why some patients had chills and others had not. In an attempt to exclude individual peculiarity the serum had been repeated in some of the cases after defervescence with no result as to chill. There was a slight chance that the chills might indicate some direct action on the pneumococcus by the serum, but they might be only incidental. He agreed with Dr. Meara that Dr. Cole should be given opportunity to study a large number of cases as his facilities could not be approached by a general hospital. In reply to Dr. Thacher he said he understood that many of the cases encountered by Dr. Cole this season were due to the pneumococcus classified as type 2. These cases seemed to be less amenable to serum treatment. In reply to Dr. Conner, it was thought by Dr. Eiser, in conjunction with whom this work was done, that a potent serum should give an immediate and definite result and that it should be unnecessary to repeat the dose. The action hoped for, however, could not be compared to that of diphtheria antitoxin as the pneumococcus did not produce a soluble toxin. In reply to Dr. Thompson the patients treated were of all kinds and ages. When the work was again taken up more help would be available for sputum and blood work. A number of pneumonia patients had been treated with vaccines in Dr. W. C. R. Williams' service at the New York Hospital with no apparent influence.

Conservatism in the Treatment of Disease.—Dr. BEVERLEY ROBINSON read this paper. (See page 199.)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 9, 1914.

Dr. WILLIAM P. NORTHRUP IN THE CHAIR.

THE evening was devoted to a symposium on whooping cough.

Blue Sclera with Fragility of the Bones.—Dr. CHARLES HERRMAN presented a child, twenty months old, with blue sclera associated with fragility of the bones. The parents of the patient were healthy and had had three other healthy children who began to walk and talk at the proper age. The patient was nursed for ten months, had digestive troubles occasionally, and was always delicate. The first teeth appeared at seven months. The patient was able to sit up at nine months, but had never been able to stand alone or to talk. In December, 1913, the child fell from a chair and fractured the right tibia. About six weeks later while in bed, the cast still applied, the child fractured the right femur. On examination, the child showed a skull with a short antero-posterior diameter and prominent brow. The sclera were distinctly blue, not of a bluish tinge such as was frequently seen in tuberculous patients, but what was known as a pale china blue. There was no marked sign of rickets. The fontanelle was closed, the child had twelve teeth, no rosary or enlargement of the epiphysis. The occurrence of blue sclera in certain patients had been noted by several English ophthalmologists, Adair, Dighton, Stephenson and others. The sclera were distinctly blue and the color was uniform throughout. Bluish patches on the sclera he had noted in a number of colored children. The English observers had reported families in which several generations showed this peculiarity. It was usually transmitted through its female members. Not all the members of the family had blue sclera and not all who had blue sclera had fragile bones; but all those who had fragile bones had blue sclera. A somewhat similar sclera was occasionally seen in congenital heart disease and might be due to a similar cause, namely, a lack of fibrous tissue, allowing the choroid to show through the thin sclera. The fragility and lack of elasticity in the bones was probably due to a similar change in structure. So far as he knew no pathological examination of the sclera and bones in these cases had been made. In his own patient the radiographic examinations were made while the leg was still in the cast so that the minute structure of the bones was not shown. Now that the cast had been removed he had another radiographic examination and would present the plates at some future meeting. An interesting question was, what relation do these cases bear to those of "osteogenesis imperfecta" or "fragilitus osseum." They appeared to bear some relation to the late cases of the latter disease. However, the condition was rare and only recently described. Without careful radiological and pathological examinations this point could not be definitely decided.

The Etiology of Pertussis.—Dr. ANNA WESSELS WILLIAMS announced that they were still only able to report that they were nearing the time when they could fully demonstrate the specific etiological factor in whooping cough. Very few cases were examined from the beginning of the disease to the end; very few cases

died in the early stages of the disease so that autopsy findings were complicated by mixed infections which seemed to be the direct cause of death in the majority of the cases. Probably no case of pertussis was uncomplicated from the beginning to the end. In order to determine the presence of specific organisms in infections in this locality one should be able to study the cases from the beginning to the end under favorable conditions for isolation and observation; cases occurring in well-to-do and intelligent families were better suited for this purpose than those occurring in poor over-crowded homes, or in institutions or hospitals. The practising physician should give them help in obtaining these favorable cases. The ideal place for the study was a special hospital where the children could be treated and studied with sufficient controls. Their studies had emphasized the truth of these observations. From their study they concluded as follows. 1. Though the Bordet-Gengou bacillus had not been found in the majority of the cases of pertussis, it had been found most frequently under the best and most significant conditions and there were sufficient reasons for not finding it under other conditions. 2. The irregular reports given to the complement fixation tests in human beings might be accounted for by the different methods used without making comparative studies and sufficient controls, and by the occurrence of distinct varieties of the species *B. Pertussis*. 3. The irregular results from vaccine treatment might be accounted for by the lack of definite group work among physicians with the establishment of a general plan and sufficient controls in each series of cases studied at the same time taking into consideration the various points still under discussion. 4. The hypothesis of Mallory that the essential lesion of pertussis was chiefly a mechanical one and could only be considered as a suggestion for further study in establishing the specificity of the Bordet-Gengou bacillus.

Dr. JOHN S. BILLINGS, representing the Commissioner of Health, Dr. Goldwater, said he had been requested to describe what the Health Department was doing in regard to whooping cough and what they purposed doing. Prior to the reorganization of the Bureau of Infectious Diseases they had not been active in combating whooping cough except to require that cases be reported and that they be excluded from the schools. Cases of whooping cough were not visited. The new plan of organization of the Department which went into effect on January 1, 1914, required the sanitary supervision of whooping cough. This will be carried out by nurses as far as possible. The first month, January, had been spent in breaking in the nurses and during February and March their time was required in handling measles and scarlet fever, so that they had had so far no time for visiting whooping cough cases. As soon as possible the nurses would visit the homes of whooping cough patients. The mothers or heads of families were sent a card describing the dangers of whooping cough and giving the precautions that should be taken to protect others from the disease. When the paroxysmal cough was no longer present the child could be re-admitted to school. A comparison of the death certificates with the cases reported showed that notification was not closely observed; they had not been drastic in enforcing this measure. The nurses would keep the children under observation and if the regulations of the Department were not observed the child would be removed to the hospital. The speaker said he hoped they would soon have a whooping cough camp for these cases. Since January 1, 1914, the Department had maintained one whooping cough clinic in Brooklyn, where during other hours a Wassermann clinic was also held. This clinic was not in a tenement district and so was not patronized to any extent. In 1913 a request from the Association of Out-Patient Clinics for information in regard to the establishment of special clinics for whooping cough cases led to an investigation which showed that of 116 institutions there were 38 to which whooping cough cases applied for treatment; 78 had no such applications. Of the 38, to which whooping cough patients applied, 34 treated the cases that applied. There were two dispensaries that used vaccine and 28 that employed drugs. Five institutions had physicians visit whooping cough patients in their homes. In reply to the question "Do you report whooping cough?" 67 institutions said that they did not, while 49 said that they did report them. In reply to the question "Do you have special postals for this purpose?" 68 institutions said they had no such postals, while 48 had them. In reply to the question as to whether they wished to establish special classes for whooping cough there were no positive answers but 15 said they would consider the question. After the requirements for classes were explained to them, 101 said they could not comply with them. An inquiry into the method of examining applicants showed that 102 of the institutions did not make any preliminary examination of applicants. The requirements of the Department for special whooping cough clinics would probably be that the quarters used for this purpose should open directly on the street; that they should not be used for any other purpose; that they should be thoroughly scrubbed and cleaned after the clinic, and the windows left open during the entire time when not in use. Such clinics should be located in the tenement districts of the poorer class as it was useless to establish a clinic unless it was within walking distance of the people who would attend it. No person having whooping cough should use a public conveyance and the same care should be exercised in handling the sputum as was employed in cases of tuberculosis.

The Clinical and Sociological Aspects of Whooping Cough.—Dr. JOHN LOVETT MORSE of Boston gave this talk in which he referred to a study that he had made about a year ago in regard to the incidence and mortality of whooping cough, the results of which were embodied in a paper read before the American Pediatric Society in May, 1913. The mortality statistics, as compiled by the United States Census Bureau in 1906 from a registration area comprising a little less than one-half of the population of the United States, showed that there were 6,324 deaths from whooping cough among children under five years of age. The reports of the United States Public Health Service show that in 1910 the death rate per 100,000 population for whooping cough was 11.4 per cent.; for scarlet fever, 11.6 per cent.; for measles, 12.3 per cent. In 1911 Dr. Morse said he had communicated with the Boards of Health of thirty states and with a considerable number of cities scattered all over the United States with reference to the relative incidence and the efforts at control of whooping cough. He had received replies from sixty-one and a comparative study of these replies showed that on the whole the death rate from whooping cough was greater in the large cities than in the small, greater in the small cities than in the rural districts. There were a large number of deaths from the complications of whooping cough which should be added to the mortality of the disease itself. The mortality of whooping cough was greater than that of scarlet fever but not greater than that from diphtheria. All the statistics showed that whooping cough was a serious and a fatal disease. In reply to inquiries as to what was being done to prevent the spread of the disease and to diminish the death rate, it was shown that there was really very little effort being made in this direction. Of the 43 states interrogated only 29 replied. In seven of these isolation was required by law and in two others "Modified isolation" was required. In only one-half of the states replying was whooping cough a notifiable disease. In regard to the mortality of the disease at different ages, a German statistician had shown that the mortality for children under one year of age was 26 8 per cent.; in children between one and two years, 23 per cent., and that it decreased in direct proportion as the age of the child increased. In this country 96 per cent. of the deaths from whooping cough occurred in children under five years of age. This made it evident where the efforts in preventive work must be directed. This inquiry showed further that there were practically no hospital accommodations for whooping cough in this country. There was a small ward in Bellevue for cases having complications; Philadelphia had somewhat better accommodations; New Orleans had a ward containing six beds; Cincinnati had one isolation building, and Johns Hopkins had a few beds. Whooping cough patients frequently came to the clinics and waited a long time among other patients and in some clinics they were allowed to come back at will. There were but two or three special clinics for whooping cough in this country. The speaker said he was under the impression that Mallory had proved conclusively that the Bordet-Gengou bacillus was the cause of whooping cough until he had listened to Dr. Williams's paper, and he still thought that for practical purposes it might be considered as much. This bacillus had been found in the sputum as late as the eighth week of the spasmodic stage and transmitted the disease through the secre-

tions of the respiratory tract. While it was possible to infect some animals with the disease this method of transmission did not play an important part in the control of the whooping cough. It was the transmission by direct contagion that was the important factor. Owing to the indefinite length of the early symptoms and the mild course of the disease in many cases, almost everyone soner or later had this affection. As a rule, however, it was only serious in young children. The isolation and recognition of the cultures were still too complicated a procedure for every day use. An agglutination reaction was present in many cases, but was not constant and usually not very high. In exceptional circumstances the complement fixation test might be of great service in the recognition of abortive and attypical cases. There was both an absolute and a relative increase in the number of lymphocytes in the catarrhal stage of the disease. This blood picture was characteristic and might be of considerable diagnostic importance. Since, aside from the Public Health Service and the pediatrists, few appreciated that whooping cough was a serious and a fatal disease the first step in combating the disease was to teach physicians and the public this fact. Whooping cough should be made everywhere a reportable disease. The house should be placarded and the inmates instructed by the health authorities as to the seriousness of this disease in infancy. The vomitus and sputum should be treated in the same way as in tuberculosis. The patient should be separated from other children in the family when the latter were under five years of age. Children might be allowed to go out of doors provided they were kept from other children. They should, however, be obliged to wear an arm band of some prescribed color on which should be placed in large letters in some prescribed color "Whooping Cough." As the vitality of the Bordet-Gengou bacillus was slight outside the body and had no tolerance of light and air formal disinfection was not necessary. Other children in the family should not be allowed to attend school unless they had already had the disease or unless two weeks had elapsed since the last exposure, and they were free from catarrhal symptoms. The community should be required to establish hospitals for children not properly isolated at home and for those who could not be properly treated in their homes. When these recommendations were carried out, whooping cough would cease to be the scourge that it now was.

The Treatment of Whooping Cough.—Dr. EDWIN E. GRAHAM of Philadelphia presented this communication; he stated that the treatment of pertussis had always absorbed a large degree of medical attention and that the mere enumeration of all the drugs and inhalations which had from time to time been brought forward, would consume more time than had been allotted to him. It was important that all children who had not had the disease should be kept separate from the individual who had it, and in order for quarantine to be effective all unexposed children should be sent away from the house during the entire period of contagion; this applied particularly to infants, to children who were not robust and to those who had a tendency to tuberculosis. All children with pertussis should be given an abundance of fresh air and should be kept in bed if their temperature was above 100° F. If the patient was sufficiently ill to be kept in bed the windows should be kept open day and night; if not in bed the child should be out of doors as much as possible. However, excitement and violent exercise tended to increase the attacks. An acute laryngitis or rhinitis, however, was not benefited by cold air. A change of air, especially to the seashore, was often of benefit and a change from a raw damp climate to one warmer and milder was often followed by improvement. Where the child had been confined to his room for a long time, a change to another room and a thorough cleaning of the room vacated was of benefit. All children with pertussis should be fed with small quantities and often; if vomiting occurred soon after a meal another feeding should be given to replace the one lost. Gastrointestinal complications in whooping cough constituted a dangerous complication and should receive early and careful dietetic and medicinal care. Local applications to the nasopharynx made in the early stages of the disease might be of decided value. An application of a 2 per cent. nitrate of silver solution to the nasopharynx, by producing death of the superficial membrane, and possibly destroying some of the specific bacilli, tended to prevent the spread of the infection to the deeper respiratory passages. Phenol, 1 per cent. had also been used successfully. It should be used early and repeated every other day. Creosote and carbolic acid used in an ordinary inhaler covering the nose and mouth or by vapor in the room of the patient acted as a sedative to the inflamed membrane and as a local antiseptic in some degree. As children were especially susceptible to carbolic acid poisoning, the urine should be watched closely. When the spasm of the glottis was especially severe intubation might be done and often gave relief. The medicinal treatment of pertussis might be divided for convenience into two parts: First, drugs which *per se* had a tendency to lessen the number and severity of the paroxysms. Second, drugs or other methods that were directed to the treatment of the complications of pertussis. Among the drugs which the author had found useful was belladonna, beginning with one drop of the tincture three times a day and increasing the daily quantity by one or two drops until mild physiological effects of the drug appeared, when the increasing of the dose must be cautiously continued. Antipyrin was a useful drug, but personally, he never used it in the large doses frequently advised. A single dose at bedtime or a dose morning and evening was as much as it was wise to employ. Bromide of sodium, five grains, three or four times a day, to a child three years of age was often of benefit; and codeine, trional, heroine, and chloral were often of benefit in allaying cough and inducing sleep. They might be given in a single dose at bed time or in two or three doses during the day. A combination of quinine, two parts, and veronal, one part, had been used successfully by Professor Winternitz of Vienna; but he believed it acted only as long as it was given and was not a cure. Sollman and Hatcher reported favorable results from a combination of quinine, one or two grains, and sodium bromide, one or two grains, repeated three or four times a day, for a child two years f age. Quinine had been given in large doses and might reduce the number and severity of the paroxysms, but it was not an antispasmodic, and if it produced any effect in these large doses it must be because of some effect on the causal bacillus. Lenzman had reported some interesting results from the giving of quinine intravenously and hypodermically. Quinine lactate, 10 grams, and saline solution, 100 grams, of which two and one-half centimeters given warm, was injected intravenously might be similarly used. If given hypodermically into the muscles the effect was favorable, but not so prompt and satisfactory if given intravenously. Hydroquinine had been employed both intravenously and intramuscularly, but its action was more favorable when injected into the vein. A daily dose was given for five or six days; then a dose every second day and it was claimed that a remarkable improvement was noted after the first week of treatment. No disagreeable local or constitutional symptoms followed these injections and so much was claimed for this treatment that it was worthy of extended trials. Hydroquinine had been used as a prophylactic with satisfactory results. Fletcher had reported favorable results with the use of adrenalin. He treated 15 cases, using two or three drops of 1-1,000 adrenalin solution every two or three hours, and claimed that in two or three weeks the patients were entirely well. He believed the rapid cure of these cases prevented the spread of pertussis and that the adrenalin exerted a specific action on the causal agent of pertussis. The psychic element often entered into the disease, especially in neurotic children. If the mother and those in contact with the nervous child were also neurotic, all the conditions were favorable for the development of marked psychic phenomena. It was quite possible in such cases to use suggestion advantageously as an aid in the treatment. The writer cited two cases which emphasized the necessity of a correct diagnosis of complications in pertussis. In regard to the vaccine treatment, a large number of articles had appeared on this subject and a close study of these together with his own cases had convinced him that the vaccine treatment was a distinct addition to their methods of treatment and it was also of more or less use as a prophylactic. In a case of moderate severity in an infant or older child, when the number of paroxysms was few and mild in character, the vaccine treatment was not necessary; but it was often of distinct benefit in severe cases in children of all ages, and its influence as a prophylactic where infants had been exposed, or where frail or

tuberculous children were infected should be carefully worked out. Dr. Graham reviewed the reports of the observers in regard to the vaccine treatment and concluded that almost all of them were favorable to the treatment, and it seemed to him advisable to use the combined vaccines in the treatment of severe cases. The final evidence as to its efficacy could only be decided by additional evidence.

The Need of Hospitals for Whooping Cough in New York City.—Dr. GODFREY R. PISEK presented this communication. He declared that if the investigation which had just been made of our Municipal Institutions had been extended to the accommodations which they had provided for cases of pertussis the survey would not have consumed much time. In this respect our municipality was no better and not much worse than other great centers of the world. Pertussis, through its commonest complication, bronchopneumonia, carried away a large number of the children of New York every year. There were in the year 1913 a total of 420 deaths from whooping cough in the Greater City. Of these 49.5 per cent. occurred during the first year of life, 33.4 per cent. between the first and second years, 8.8 per cent. between the second and third years, and 5.2 per cent. between the third and fourth years. Only 1.2 per cent. of the mortality occurred after the age of five years. It was a well-known and deplorable fact that many children succumbed to tuberculosis following their paroxysmal attack. The incidence and mortality of whooping cough in Greater New York during the past few years was as follows: In 1910 there were 2018 cases with 294 deaths; in 1911 3,210 cases, with 384 deaths; in 1912, 2,132 cases with 287 deaths; in 1913, 3529 cases with 420 deaths. During 1913 there were 1333 deaths from diphtheria, 628 from measles, 507 from scarlet fever, and 420 from whooping cough. In children under the age of five years there were more attacked by whooping cough than by scarlet fever and the mortality was almost as high. There were ample hospital provisions for typhoid fever and yet there were only twelve children under the age of five years who had typhoid fever in the year 1913. There were in New York City 1884 available beds for infants and children in the public and semi-private hospitals, and 2350 beds in the various hospitals for contagious diseases; yet of these there were only 10 set apart at Bellevue for cases of whooping cough with complications, and 30 at the Metropolitan Hospital. If whooping cough had been born with some kind of a rash it would not now need any advocates to point out the dangers with which it was attended. As things were the laity regarded this disease as not particularly dangerous and the physician often fostered the same idea, so that it received comparatively little medical attention until the patient had serious and often fatal complications. Believing that many cases were not reported and that many more did not reach the physician, they had made an investigation of the deaths attributed to whooping cough and found that of every 63 deaths from this cause only one had previously been reported to the Department. The figures of the Department of Child Hygiene relating to contagious diseases reported by the inspectors in the schools or found at home were significant in this connection. In 1912, 372 cases of whooping cough were found at school and 466 by absentee visits, making a total of 838. In 1913, 290 were found in school and 445 by absentee visits, making a total of 735 cases. The reason that whooping cough was not more effectually controlled by the Health Department was because of certain difficulties which differentiated it from other contagious diseases. The comparatively long first stage in which the diagnosis was often uncertain for days, and the long duration and questionable period of "Safety for others" made the disease difficult to handle from the Department standpoint. In attempting to formulate any plan for better control the valid objections to general hospital care must be recognized, but there was still much to be said in favor of hospital care for cases with complications and segregation of others affected with the disease. There were in our large population cases of whooping cough in families who were unable to provide medical care because of poverty. These were compelled to go to the dispensaries, where, after waiting and mingling with other children, they were singled out as Pariahs and sent home, often untreated because of lack of suitable provisions and with no instructions as to the care and prevention of the spread of the disease. Where the mother was the breadwinner and the Day Nursery refused to care for the child, a serious economical question was involved. Again, an infant with bronchopneumonia, who needed judicious stimulation, skilled nursing, and an abundance of fresh air was deprived of these and allowed to die in a tenement for lack of municipal facilities. If an intensive study of the disease were made in a selected section of the city it seemed certain that many more cases of whooping cough would come to light than had been reported. Such a study would furnish an accurate basis upon which hospital beds could be apportioned. At the present time there were no suitable available buildings. These should be built on the open pavilion plan near the water fronts, and especially designed for this purpose; at least one for each borough. Disused ferry boats or barges moored to the city docks could be utilized for this purpose; on these a small hospital ward could be arranged for those needing medical attention. Dispensaries for ambulance cases could be held there and to these places patients from other clinics could be referred. Children with their mothers could be taken in stages provided by the city to these boats and allowed to spend the day out-of-doors, returning to their homes at night. With such a plan a large number could be educated to follow proper methods of prevention and well children could be spared contact and deaths from complicating conditions prevented. In regard to the prevalence of the disease in this section Dr. Pisek said that his own histories of his last 500 patients under 10 years of age showed that 45.8 per cent. had had whooping cough. There could be little question but that provision for whooping cough cases would promote the public welfare and at the same time would give physicians an opportunity to study the disease as to its early diagnosis, and to perfect treatment along more scientific lines. To this end the writer suggested that a committee be appointed who should present to the Health Commissioner a recommendation urging the establishment of wards for urgent cases of pertussis, and segregation centers for uncomplicated cases.

Dr. JOHN WINTERS BRANNAN said that they would have to acknowledge that their provisions for the care of whooping cough patients were inadequate. Bellevue had ten beds for complicated cases and the Metropolitan Hospital made provision for a few cases. The meeting this evening was one of the most important from the standpoint of public health that they had had for years. He had not realized that conditions were as bad as they had been shown to be. It was to be regretted that they had failed in the attempt to moor the boat *Helen C. Guilliard* off Willard Parker Hospital, but he hoped they would have a boat next year. There were few places around Manhattan suitable for a whooping cough boat as it was necessary to have such a boat near a hospital.

Dr. ROWLAND G. FREEMAN said that they were greatly indebted to Dr. Morse and Dr. Graham for their valuable contributions. Concerning what Dr. Morse had said in regard to the spread of whooping cough he would like to emphasize the point that it was difficult to limit the spread of this disease during the first two weeks as it was often impossible to make a definite diagnosis. Two points, however, were of great value: these were a persistent increasing cough without other catarrhal symptoms and a high lymphocytosis. If a child over three years of age with a suspicious cough showed a lymphocytosis approaching 50 per cent. the diagnosis was fairly certain. While infant mortality and general mortality had markedly diminished in recent years contagious diseases showed little diminution. This was because the diseases were largely spread by the schools and no effective action had been taken to prevent their spread. This could only be prevented by keeping children who had been thoroughly exposed to contagious disease away from school during the latter part of the period of incubation, and such rules were now in force in the best private schools in New York.

Dr. CHARLES GILMORE KERLEY said that the mortality statistics for whooping cough did not give a proper impression of the extent of the ravages of that disease as it played an important part in diminishing the resistance of the child and thus lessened its chances of surviving the diarrheal diseases of summer. The same was true with reference to tuberculosis; with the diminished resistance following whooping cough the child more readily fell a victim to this affection. As to isolation, if the child was taken out of school it went into the street and there mingled with other children and attempts to isolate the child in the family were futile since by the time that a diagnosis of whoop-

ing cough could be made every other child in the family had been exposed. Mild cases were very difficult to diagnose. Dr. Kerley said he agreed with what had been said in regard to changing the room of the whooping cough patient, it was a great advantage for the child to have a different room to sleep in from the one occupied during the day. The statement was made that with the nitrate of silver treatment all patients improved after three or four weeks; any case would be better by that time. He had found quinine alternated with bromide of sodium and antipyrine very acceptable. In an interview with Dr. Freeman last summer he had found that Dr. Freeman was not so enthusiastic in regard to the vaccine treatment as Dr. Graham's statistics would lead one to suppose. Dr. Freeman had said, however, that the vaccines did no harm. His usual dose was two hundred million twice a week. He had used the pneumococcus vaccine with these and thought this an advantage in preventing pneumonia.

Dr. Matthias Nicoll, Jr., said that he had read all the reports in regard to the value of the vaccine treatment but had never seen one in which an analysis of the case records as given, convinced him of the great value of the remedy, although many of the writers drew favorable conclusions hardly warranted by the statistics. From what Dr. Williams had said of the probable variable nature of the infecting organism, it was logical to expect variable results with the employment of stock vaccine. Very great differences in the clinical course of the disease, as well as the character of the prevailing epidemics, made the reports of a few cases of little value as a means of judging the specific action of the remedy, especially if controls were not used in practically every case. In the last analysis, the strictest test of the value of a specific remedy must be its power to prevent a disease and a vaccine that could not do this could hardly be expected to overcome a disease when once established. A small number of cases had been reported in which such a protective action seemed to have been established. However, the number of such instances was by no means sufficiently large to warrant positive conclusions, for it must be remembered that all children did not take the disease even when very fully exposed to it. For instance, Dr. Nicoll had gone into a children's ward in which the forty or more occupants had lived for three or four months during which about thirty of the children had contracted the disease while the others, most of whom were from one to two years of age, escaped in spite of the closest and most constant contact. The contemplated immunity experiment in this instance was naturally abandoned. During the past eight months at the Research Laboratory about eighty cases of whooping cough had been treated with vaccines and the course of the disease followed as carefully as circumstances would permit. The cases had been treated in institutions, in clinics, in their homes, either by members of the laboratory staff or by private physicians and hospital staffs. Three strains of vaccines had been used, the first made from imported Bordet-Gengou strains combined with three strains of hemoglobinophilic organisms isolated from cases of whooping cough, the second made from the same imported organisms combined with two strains of somewhat atypical Bordet-Gengou organisms from local cases giving a similar complement fixation reaction as the former, and third, four strains of typical Bordet-Gengou organisms isolated from local cases. The results of treatment had varied markedly. A number of cases showed very distinct and rapid improvement; others seemed to be little affected. The mild character of the symptoms observed since the early autumn had done much to prevent a definite opinion as to the real value of specific treatment, many cases not treated running a very favorable course. In brief it might be said that there was an indication of value in many of the cases treated with vaccine, but in order to form a really definite opinion it would be necessary to treat many more cases and to have the children under observation such as would render the clinical reports of much more value than they had hitherto possessed. The present lack of effort to control and care for the disease was a disgrace to the community and it was to be hoped that the Department of Health would continue to direct its attention to this problem. The setting aside of ten additional beds was little more than an entering wedge. He thought he voiced the opinion of every physician who had the welfare of the community at heart when he stated that the authorities should take action immediately to solve the problem of a disease which killed nearly five hundred children in the City of New York during the past year and especially that provisions should be made for the care of young children having whooping cough complicated by pneumonia and unable to be placed under the care of a private physician.

Dr. Haven Emerson said he had come to listen and not to speak, but he could assure them that the activities of the Health Department would be increased along this line.

Dr. S. J. Meltzer asked Dr. Williams whether the statement he had heard made that Mallory was dealing with the *B. bronchosepticus*, that was, the distemper bacillus, instead of the bacillus of Bordet-Gengou was true.

Dr. Anna M. Williams replied that as she had stated in her paper, Mallory had said that his animal experiments were not sufficiently controlled; that possibly the animals might have had the *B. bronchosepticus*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of the State of North Carolina.

June 10-14, 1913.

(*Concluded from page* 132.)

PRACTICE OF MEDICINE.

1. What is aphasia? (*a*) What is the difference between sensory and motor aphasia? (*b*) Where is the central lesion in motor aphasia located?

2. What is multiple neuritis? (*a*) Give etiology, diagnosis, and prognosis.

3. What is diabetes? (*a*) What are the modern theories concerning its etiology? (*b*) Discuss the carbohydrates in the treatment.

4. Describe briefly the character and situation of pain in gastralgia, ulcer of the stomach, lead colic, general peritonitis, appendicitis, gallstone colic, and kidney colic.

5. What are the chief causes of secondary anemia? (*a*) How would you differentiate secondary anemia from primary pernicious anemia?

6. Define aneurysms. How may they be classified? (*a*) How would you differentiate between aneurysm of the ascending and transverse aorta?

7. What are the chief causes for obstruction of the common bile duct producing jaundice? (*a*) Give the clinical manifestations produced by obliteration at Vater's ampulla.

8. Define pellagra. (*a*) Give the clinical history. (*b*) Give the most recent treatment, and the mode of administration.

GYNECOLOGY AND OBSTETRICS.

1. Source, composition, and specific gravity of liquor amnii.

2. Discuss briefly the physiology of the transmission of insanity, feeble-mindedness, or other mental or moral traits or characteristics, or physical defects, or characteristics from parent to offspring. Give Mendel's formula for heredity.

3. What constitutes the pelvic floor?

4. What are some of the indications for producing sterility in a woman and describe the proper operation.

5. Differentiate uterine polypus and chronic inversion of the uterus, and give proper treatment in each case?

6. (*a*) What is the normal course of delivery in occipito-posterior position? (*b*) In case the normal course is not followed, what is the method of delivery? (*c*) And in the latter case what is the percentage of mortality to mother and child?

7. (*a*) What are some of the diseases of the breast liable to occur during the puerperium? (*b*) What is the treatment for each? (*c*) What prophylactic measures should be instituted?

8. (*a*) State some of the indications, and (*b*) describe what you consider the best operation for emptying the uterus at the second month of uterogestation, (*c*) at the sixth month.

Answer only six questions.

SURGERY.

1. Name every disease or condition (occurring to you), involving the genitourinary tract, which might produce hematuria

2. Describe the operative technique of a resection of the elbow joint, naming the important structures to avoid.

3. Name: (*a*) The varieties of dislocation of the shoulder joint. (*b*) Diagnostic symptoms of a subcoracoid. (*c*) Technique of reduction of a subcoracoid.

4. Give the surgical guides for the location of the lingual artery, for the purpose of ligation.

5. How would you treat a compound fracture of the tibia at its middle third?

6. Give symptoms and treatment of an osteomyelitis of the tibia.

7. Define (*a*) chancroid, or soft chancre. (*b*) How would you treat a chancroid or soft chancre of the penis? (*c*) What is its incubation period?

8. Describe the operative technique, of a tracheotomy

ANSWERS.

PRACTICE OF MEDICINE.

1. *Aphasia* is partial or complete loss of the power of expressing or of understanding spoken or written language; it is due to a cortical lesion and not to peripheral lesions. Loss of power to produce the various movements necessary to speech is called *Motor aphasia;* loss of memory for words, or inability to perceive and interpret words is called *Sensory aphasia.* In motor aphasia the central lesion is located in Broca's convolution (on the left side in right-handed people).

2. *Multiple neuritis* is an inflammation of a number of nerves either simultaneously or in rapid succession. It may be due to poisons (alcohol, lead, arsenic), or diseases (syphilis, sepsis, gout, diabetes, malaria, diphtheria), or general malnutrition. It may begin insidiously, and is generally characterized by numbness or tingling in hands and feet, cramps, disturbances of sensation and motion, wasting and paralysis; the distinctive feature is the symmetrical location of the symptoms. Treatment consists in removal of the cause (if possible), general tonics, morphine for the pain, bromides or chloral for the insomnia, strychnine for the paralysis; massage and electricity are useful.

3. *Diabetes* (*mellitus*) is a constitutional disease characterized by polyuria, excess of sugar in the blood and excretion of the same in the urine, and accompanied by severe emaciation.

Etiological factors are said to be:—Age between 40 and 60, Jewish race, worry, nervous strain, and lesions of the pancreas. In the *treatment*, carbohydrates should be gradually removed from the diet until either the urine is free from sugar or the diet is free from carbohydrates. When the urine is free from sugar, carbohydrates may be gradually resumed, but must be reduced or stopped on the re-appearance of sugar in the urine.

4. In *gastralgia*, the pain is sudden, and burning, boring, tearing or lancinating, originating in the epigastrium and radiating in various directions.

In *ulcer of the stomach*, the pain varies from a gnawing sensation to a feeling of soreness in the epigastrium or a painful sense of lump or oppression. It is usually located in the epigastrium, more rarely in one or the other hypochondriac region, with a tendency to run to the back. The pain may occur within fifteen to twenty minutes after the ingestion of food, or it may be deferred until one or two hours after eating.

In *lead colic*, there is a violent outbreak of spasmodic abdominal pain. It may be chiefly umbilical, or epigastric, or diffuse over the entire abdomen.

In *appendicitis*, the pain may occur two or three hours after eating and may be relieved by eating. The location of the pain, roughly speaking, is epigastric, but lacks the accurate localization that is seen in ulcer. In many cases the pain is felt lower down in the abdomen below or to the right of the navel, and even though the pain may originate in the epigastrium radiation downward toward the umbilicus or lower abdomen may occur.

In *gallstone colic*, the pain is immediate, severe, and lancinating, appearing suddenly in the epigastrium and radiating to the right and upward or to the right side of the back. The pain is continuous, with periods of intense exacerbation, and is uninfluenced by food, fluids, or alkalies.—(From Lockwood's *Diseases of the Stomach.*)

In *peritonitis*, the pain is at first local and corresponds to the seat of the primary lesion, but soon becomes diffused and general. Except when due to perforation of a gastric ulcer, when it is referred to the chest, back, or shoulder, the greatest pain is below the navel. The pain is increased by pressure or movement.

In *renal colic*, the pain is sudden and agonizing, having its origin in the lumbar region, and following along the course of the ureter. It is felt also in the testicle and down the inner side of the thigh, and is at times referred to the glans penis. It may last only a few minutes or for hours.—(From Butler's *Diagnostics of Internal Medicine*).

5. *Cause of secondary anemia:* Hemorrhages, nephritis, cancer, suppuration, tuberculosis, malaria, poisons (such as mercury), syphilis, and very high fevers.

Secondary anemia has an ascertainable cause; and a blood examination shows the red cells reduced to about 1,000,000 to the cubic millimeter, a relatively low hemoglobin estimate, a few normoblasts and megaloblasts, and the white cells generally increased in number.

Primary pernicious anemia has no ascertainable cause; and a blood examination shows a marked reduction in the number of red cells, but a relatively high hemoglobin estimate; nucleated red cells are quite common; and the white cells are generally decreased.

6. An *aneurysm* is a pulsating sac containing blood, and communicating with the lumen of an artery. Aneurysms may be classified as:—true, false, and dissecting; also fusiform, and sacculated.

ANEURYSM OF ASCENDING AORTA.	ANEURYSM OF TRANSVERSE AORTA.
Physical signs. Pulsation often expansile, in second and third interspaces.	Pulsation in episternal notch.
On palpation, systolic thrill and diastolic shock to right of sternum.	Systolic thrill in episternal notch.
Dullness to right of sternum, above cardiac area.	Dullness over manubrium sterni.
Rough systolic murmur, loud clanging second sound. May have diastolic murmur from implication of aortic valve.	Murmur more distinct over manubrium. Diastolic murmur rare.
Parts liable to pressure and results of pressure. Vena cava superior; dilated superficial veins, edema of head and neck.	Left innominate vein; edema of left side of head and neck.
Innominate artery: weakness of right radial pulse.	Any branch of the arch; weakness of right or left radial pulse.
Heart; downward displacements of apex.	
Ribs to right of sternum; pain.	Manubrium sterni; pain.
Right bronchus; defective respiration on right side.	Trachea or left bronchus; paroxysmal dyspnea, altered cough, defective respiration on left side.
Right recurrent laryngeal (rarely); paralysis of right vocal cord.	Left recurrent laryngeal; paralysis of left vocal cord.

—(Wheeler and Jack's *Handbook of Medicine.*)

7. Obstruction of the common bile duct produces jaundice because the bile being unable to pass from the liver into the intestine is absorbed into the hepatic vein, and carried into the general circulation. The causes of jaundice from mechanical obstruction of the bile-duct, are given by Murchison as follows:—

(*a*) *Obstruction by foreign bodies within the duct:* Gallstones and inspissated bile; hydatids and distomata; foreign bodies from the intestines.

(*b*) Obstruction by inflammatory tumefaction of the duodenum, or of the lining membrane of the duct, with exudation into its interior.

(*c*) Obstruction by stricture or obliteration of the duct: Congenital deficiency of the duct; stricture from perihepatitis; closure of the orifice of the duct in consequence of an ulcer in the duodenum; stricture from cicatrization of ulcers in the bile ducts; spasmodic stricture.

(*d*) Obstruction by tumors closing the orifice of the duct, or growing in its interior.

(*e*) *Obstruction by pressure on the duct from with-*

out, by: Tumors projecting from the liver itself; enlarged glands in the fissure of the liver; tumors of the stomach, duodenum, pancreas, kidney, or omentum; abdominal aneurysm; accumulation of feces in the bowels; pregnant uterus; ovarian and uterine tumors.

The *clinical manifestations* are: Jaundice or discolored skin, some of the secretions are tinged with bile or contain bile pigment, there may be a bitter taste in the mouth, the digestion is disturbed, pruritus is generally present, there may be skin eruptions, xanthopsia is present, and there may be some cerebral symptoms; in addition to these, the inability of the pancreatic juice to reach the intestine will cause fatty stools, emaciation, and glycosuria.

8. *Pellagra* is a chronic specific disease, probably infectious, characterized locally by erythema involving usually the exposed portions of the body surface and recurring from year to year during the summer months; characterized constitutionally by symptoms involving the gastrointestinal tract and the mental and nervous systems. Languor and debility are frequent prodromata. Bacteria, maize, metazoa and protozoa have all been supposed to be the main etiological factor. The skin symptoms are the most striking, most constant, most characteristic and most important from a diagnostic standpoint. In their absence, a diagnosis of pellagra is unwarranted. The eruption usually appears suddenly as an erythema, irregular in outline, involving most frequently the dorsal aspect of the hands. It is symmetrical, and may encircle the wrists or appear on the face. The skin becomes pigmented and thickened. Digestive disorders and dysentery often appear; and mental depression, insomnia, headache, vertigo, and tremors may be present. Treatment is chiefly symptomatic; arsenic (Fowler's solution or atoxyl) has been recommended.—(*Pocket Cyclopedia.*) The most recent methods of treatment are: "Organo-polymineralized serum"; salvarsan (intravenous injection); and direct transfusion of blood.

GYNECOLOGY AND OBSTETRICS.

1. The *liquor amnii* consists chiefly of water, but contains small amounts of albumin, epithelial cells, urea, phosphates, chlorides, etc. Its specific gravity is about 1.001 to 1.008. Its source is unknown; it is probably derived from the amnion, by transudation from the maternal vessels of the placenta.

2. "*Menael's formula* may be set down as follows: if D represent a plant with the dominant red and its germplasm, and R one with the recessive white and its germplasm, then the first generation of crosses of D and R will all be DR, and if these DR individuals be crossed the result will be $x\ (DR + DR) = x\ (DD + 2DR + RR)$, or in other words, a dominant crossed with a recessive gives in the second generation, as regards this one particular feature, one dominant, two hybrids, and one recessive, and of these, each dominant will give nothing but dominants, each recessive nothing but recessives, and each hybrid the same proportion of dominant, hybrid, and recessive."—(Adami and McCrae's *Text-Book of Pathology*).

3. The *pelvic floor* is composed of skin, connective tissue, pelvic fascia, perineal fascia, levator ani, coccygeus, sphincter ani, transversus perinei, constrictor vaginæ, and triangular ligament.

4. *Some of the indications for producing sterility in a woman* are: Excessive pelvic deformity rendering delivery of a living child either impossible or decidedly dangerous to the mother; advanced tuberculosis.

The operation may be a ligature and division of the two Fallopian tubes.

5.

INVERSION OF UTERUS.	UTERINE POLYPUS.
1. No pedunculated attachment to uterus.	1. Attached to uterine wall by broad surface or by narrow pedicle.
2. Uterine cavity being obliterated, sound can be passed but short distance, in incomplete and not at all in complete inversion.	2. Sound passes by the side of the mass through external os far into uterine cavity.
3. Vaginal or rectal conjoined examination shows a ring or depression where the uterus should be, and fails to show the uterus above the vagina.	3. Uterus felt above vagina.
4. The inverted uterus is a symmetrical pyriform body.	4. Not usually symmetrical and may be very asymmetrical.
5. Orifices of the Fallopian tubes usually demonstrable.	5. Not present.
6. Muciparous glands of the uterus present and microscopially demonstrable.	6. Not present, or if present less perfectly developed.

(Dudley's *Gynecology*).

In *chronic inversion of the uterus*, the patient is anesthetized and the uterus is reduced and kept in place by means of a repositor. Sometimes a celiotomy must be performed to allow of the reduction; and sometimes amputation of the uterus is expedient.

Uterine polypus will require dilatation of the cervix and removal of the polypus by cutting through the pedicle.

6. *The normal course of delivery in occipito-posterior positions*, is the same as in occipito-anterior positions except that the head must rotate to the front through three-eighths of a circle; of course this takes longer and is more tedious.

In abnormal cases, the management is as follows:

"(*a*) *When diagnosed while the head is at the brim.* (1) Leave it alone. The occiput will probably rotate to the front all right if it is given plenty of time. (2) If flexion appears to be deficient, try to increase it by pushing up the sinciput with the fingers in the vagina during a pain, at the same time pressing down upon the fundus with the other hand. (3) The head may be rotated by passing the hand into the vagina and grasping it between the fingers and thumb. At the same time the shoulders must be rotated by abdominal palpation, or else the head will at once go back to its original position. This maneuver requires an anesthetic.

"(*b*) *When diagnosed after the head has entered the pelvis.* (1) Leave it alone. After exercising the patience of all concerned, it will probably rotate spontaneously. Only about one case out of twenty fails to do so. (2) An attempt may be made to increase flexion as before. (3) Manual rotation may be attempted as before, but the head must first be flexed and gently pushed back out of the pelvis. (4) If the pains are weak, forceps should be applied well back on the head, so that when traction is applied, flexion will be promoted. The head should then be pulled well down on to the pelvic floor. If it begins to rotate, take off the forceps and leave the rotation to nature, merely keeping the head on the pelvic floor by pressure on the fundus. After rotation the forceps may, if necessary, be reapplied and delivery completed.

"(*c*) When the occiput has definitely rotated into the hollow of the sacrum, and the case has become a persistent occipitoposterior, forceps should be applied and the head delivered with the occiput posterior. The perineum should be guarded as much as possible, and any tears stitched up at once. In extreme cases craniotomy and pubiotomy may require to be considered."—(Johnstone's *Textbook of Midwifery.*)

In the latter case, the maternal mortality is *nil*; the fetal mortality is about 12 to 15 per cent.

7. *Diseases of the breast liable to occur during the puerperium* are: Engorgement, inflammation, abscess, and cracked nipple.

Engorgement is treated by giving the patient salines, limiting the amount of fluid ingested, and compressing the breasts with a binder. *Inflammation* is treated by resting the part, supporting it, applying a hot boracic acid fomentation, nursing from the affected breast should be stopped at once. *Abscess* is treated by making an incision radiating from the nipple, and drainage; thorough antiseptic and aseptic precautions must be observed; the breast should be put at rest for a couple of days; saline cathartics may be necessary, also supportive measures. *Cracked nipples* require to be kept clean and dry; they may be protected by a nipple shield while the infant is nursing; an application of tannic acid, or nitrate of silver may be used.

Prophylactic measures consist in not touching the breasts (by doctor or nurse or patient) without thoroughly clean hands; by washing and drying the nipple before and after nursing, and by proper attention to hygienic conditions before labor, and the nipple and breasts being preserved from pressure.

8. *The indications for emptying the uterus* are: "Intractable toxemia of pregnancy, chronic nephritis, extensive vascular degeneration of the chorion, irreducible retroversion of the pregnant uterus, absolute contraction of the pelvis, death of the fetus, chorea, pernicious anemia or leucemia.

"*At two months*, the operation can be carried out at one sitting by the method of dilatation by graduated bougies. This is carried out exactly as for a curettage. The genitals are cleansed and shaved, the vagina washed out, and the cervix fixed and drawn down by vulsella. The dilators are then passed in one after the other until the cervix admits one or even two fingers. The ovum is then separated, and extracted by the fingers or an ovum forceps.

"*At six months* the patient is anesthetized and placed in the lithotomy position. After the external parts have been scrubbed, the operator puts on boiled gloves and washes out the vagina. The cervix is then exposed by the speculum and drawn down by the vulsella. If necessary the os may be dilated by one or two Hegar's dilators sufficiently to admit the finger, which is then swept round the lower uterine segment and the membranes separated. One bougie is then gently introduced between the membranes and the uterine wall, great care being taken not to rupture the membranes. If difficulty is met with in passing the bougie, force must not be used, as the obstruction is probably due to the edge of the placenta. The bougie must be withdrawn and inserted in another direction. If no obstruction is encountered, the bougie should be passed in as far as it will go, which usually leaves about an inch or so projecting outside the cervix. A second and even a third bougie may be introduced in like manner. The ends of the bougies are then wrapped in sterile gauze and left in the vagina, which is lightly packed. The patient is kept in bed afterwards. Labor may be expected in about twelve hours, although it may start within half an hour, or be postponed for thirty-six hours, or even a day or two. Hot vaginal douches may be given every few hours in the meantime. If labor has not ensued after forty-eight hours, the bougies should be withdrawn, the vagina well douched, and either a fresh set of bougies introduced or the cervix tamponed with sterile gauze soaked in glycerin. If labor ensues after the introduction of the bougies they should be left *in situ* until expelled by the uterus. If removed too soon the labor may stop and the pains pass off again."—(Johnstone.)

SURGERY.

1. *Hematuria may be produced by:*—Inflammation, congestion, contusion of kidney, ureter, or bladder; stone in kidney, ureter or bladder, catheterization; tumors of bladder or kidney; urethritis; traumatism; purpura; hemophilia; scurvy; metallic poisons; the *Bilharzia hæmatobia:*

2. *Resection of the elbow-joint:*—"The patient is supine, but inclining to the sound side, the affected arm being held almost vertical, with the forearm flexed and nearly horizontal. The incision is made on the posterior surface of the joint. A single posterior incision is usually employed. An incision is made a little internal to the long axis of the olecranon, beginning two inches above and terminating two inches below the tip of the olecranon. This incision goes down to the bone, and throughout the entire operation the surgeon must guard and shield the ulnar nerve. The periosteum and soft parts are well separated; the olecranon is sawn off; forced flexion exposes the joint cavity freely, and enables the surgeon to lift the periosteum and soft parts from the humerus; the humerus is sawn through at the beginning of its condyloid processes; the radius and ulna are cleared and are sawn at a level below that of the base of the coronoid process of the ulna. Diseased tissues are cut and scraped away; the wound is irrigated, sutured, drained, and dressed. In some cases an H-shaped incision is employed, but the cicatrix of a transverse cut will limit flexion of the limb." (Da Costa's *Surgery.*) The ulnar and posterior interosseous nerves are to be specially guarded.

3. The *various dislocations of the shoulder-joint* are: (1) Subcoracoid—forward, inward, and downward. (2) Subglenoid—downward, forward and inward. (3) Subspinous—backward, inward, and downward. (4) Subclavicular—forward, inward, and upward.

"In *subcoracoid dislocation*, the head of the bone lies below the coracoid process upon the neck of the scapula. The tendon of the subscapularis is torn or stretched over the neck of the humerus. The supraspinatus, infraspinatus, and teres minor are either tightly stretched, producing external rotation, or torn (sometimes with great tuberosity), with internal rotation There will be found: Local contusion; restricted mobility; flattened outer border of shoulder; head of the bone is felt below outer end of clavicle; elbow is displaced from the side outward and backward, and cannot touch the chest wall when the hand is placed on the opposite shoulder; there is little or no shortening. *Treatment:*—Kocher's method: Anesthetize. Elbow is held to the side. Hand is brought forward and outward, so as to externally rotate the humerus and relax the external rotators. Elbow is adducted to the mid-line—this makes the margins of the gap in the capsule tense Elbow is raised, so as to slacken upper margin of the rent and keep lower tense. Hand is placed on the opposite shoulder, *i.e.* arm is rotated inward, to make the head of the humerus slip into capsule. Elbow lowered."—(Groves' *Synopsis of Surgery.*)

4. *In ligation of the lingual artery:* "The incision is a curved one two inches long, its concavity directed upward from the anterior edge of the sternocleidomastoid muscle, half an inch above the great horn of the hyoid bone, to a point one inch within the median line of the neck. Divide the skin and platysma, displacing the superficial veins, and open the deep fascia, when the submaxillary gland will be exposed; this is displaced upward with the handle of the knife, when the tendon of the digastric muscle attached to the hyoid bone, and the hypoglossal nerve will be exposed; next divide the fibers of the hyoglossus muscle midway between the hypoglossal nerve and the hyoid bone, and the lingual artery will be exposed. The needle should be passed around the vessel from above downward, in order to avoid the nerve."—(Wharton.)

5. "In the treatment of compound fractures the main object is to render the wound aseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, the limb shaved, and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle, and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced after enlarging the wound in the skin, or a portion sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought accurately into position it is well to fix them by some mechanical appliance: but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage tube is inserted, and, if need be, counter-openings are made; the external wound is closed or not, according to circumstances, and dressed, and suitable splints are then applied."—(Rose and Carless.)

6. ACUTE INFECTIVE OSTEOMYELITIS. "*Symptoms.*—The disease begins with a rigor, high temperature, and severe pain. The part becomes swollen, infiltrated, and congested, with distended veins over it. The pulse is rapid and small and the tongue dry, and delirium soon comes on. It should be distinguished from acute rheumatism by the fact that the interarticular and not the articular region is affected. Fluctuation can be detected if the bone be superficial, or the abscess may burst on the surface. The bone is then found to be bare over the extent of the abscess cavity. When the bone is deeply seated or the disease confined to the medulla, the swelling is later in evidence, but the pain and toxemia are very severe, and the patient may die from this before local signs show themselves. When the epiphysis is attacked, septic arthritis often quickly follows, and a loose flail joint may result.

"*Treatment* must be very prompt. A free incision must be made through the periosteum and the pus evacuated. In any case, whether pus is found or not, the surface of bone must be gouged away to expose the medulla freely, and any gangrenous tissue scraped out The cavity must then be washed out and freely drained. The wound in the soft structures is not closed in any part. If symptoms of pyemia occur, it

may be necessary to amputate the limb through the joint or bone above, so as to cut off the source of emboli. When a large portion of, or the whole diaphysis is necrosed, there are two courses; either to cut short the disease by removing the dead portion at once, or to leave the sequestrum to stimulate the formation of an involucrum. Where there is a single bone, as in the arm and thigh, the sequestrum is left; where there is a double set of bones, as in the forearm and leg, the sequestrum is removed at once. Celluloid, zinc, and ivory rods have been inserted to stimulate osteogenesis. In most cases it is doubtful how much bone is actually dead, so that it is better to open up the cloacæ in the newly formed involucrum to remove the sequestrum. The cavity heals by granulation."—(*Aids to Surgery.*)

7. A *chancroid* is an ulcer, usually of venereal origin, due to infection with the bacillus of Ducrey.

Chancroid of the penis may be treated by being sprayed with peroxide of hydrogen, dried with cotton, then touched with pure carbolic acid and then with pure nitric acid; afterwards a dressing soaked with black wash may be applied. The penis should be soaked in hot salt water every few hours, the above treatment being repeated.

The *incubation period* is about five to ten days.

8. *Tracheotomy*:—"The patient is placed on the back with a narrow pillow under the neck. Chloroform or cocaine can be used as anesthetics. An incision, one and a half inches long, is made downward from the cricoid cartilage, keeping strictly in the mid-line. The incision is deepened till the trachael rings and isthmus are exposed. Enlarged veins give trouble during this stage if there is dyspnea. A director-hood is thrust into the trachea, and the point of a knife is slid along the groove to open the trachea from below upward. The patient is allowed to cough for a few minutes while the wound is kept open with dilating forceps; then the tube is tied in."—(*Aids to Surgery.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 12
Arizona*	J. W. Thomas, Phoenix	Phoenix	Oct. 6
Arkansas	W. S. Stewart, Pine Bluff	Little Rock	
California	C. B. Pinkham, Sacramento	Los Angeles	
Colorado	David A. Strickler, Empire Building, Denver	Denver	Oct. 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 10
Delaware	J. H. Wilson, Dover	Dover	
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	Oct. 13
Florida*	E. W. Warren, Palatka	Palatka	Dec. 2
Georgia	C. T. Nolan, Marietta	Atlanta	Oct. 13
Idaho*	J. F. Schmershall, Jerome	Wallace	Oct. 6
Illinois	C. S. Drake, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	
Iowa	G. H. Sumner, Des Moines	Des Moines	Sept. 10
Kansas	H. A. Dykes, Lebanon	Topeka	Oct. 13
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	E. L. Leckert, New Orleans	New Orleans	Oct. 20
Maine	F. W. Searle, Portland	Portland	Nov. 10
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 8
Massachusetts*	W. P. Bowers, State House, Boston	Boston	Sept. 8
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 13
Minnesota	T. McDavitt, St. Paul	Minneapolis	Oct. 6
Mississippi	S. H. McLean, Jackson	Jackson	Oct. 13
Missouri	J. A. B. Adcock, Jefferson City	Kansas City	Sept. 28
Montana*	Wm. C. Riddell, Helena	Helena	Oct. 6
Nebraska	H. B. Cummins, Seward	Lincoln	Aug. 12
Nevada	S. L. Lee, Carson City	Carson City	Nov. 2
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	
New Jersey	H. G. Norton, Trenton	Trenton	Oct. 20
New Mexico	W. E. Kaser, East Las Vegas	Santa Fe	
New York	H. H. Horner, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	Sept. 22
N. Carolina	B. K. Hays, Oxford	Raleigh	
N. Dakota	G. M. Wilhamson, Grand Forks	Grand Forks	
Ohio	Geo. H. Matson, Columbus	Columbus	Dec.
Oklahoma	J. W. Duke, Guthrie	Oklahoma City	
Oregon	B. E. Miller, Portland	Portland	Jan. 5
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia	
Rhode Island	G. T. Swarts, Providence	Providence	Oct. 6
S. Carolina	H. E. Boozer, Columbia	Columbia	June 8
S. Dakota	P. B. Jenkins, Waubay	Deadwood	
Tennessee	A. B. DeLoach, Memphis	Memphis, Nashville, Knoxville	May
Texas	W. L. Crosthwaite, Waco	Waco	Nov. 10
Utah	R. W. Fisher, Salt Lake City	Salt Lake City	Oct. 5
Vermont	W. Scott Nay, Underhill	Montpelier	Jan. 12
Virginia	J. N. Barney, Fredericksburg	Richmond	Dec. 15
Washington*	C. N. Suttner, Walla Walla	Seattle	
W. Virginia	S. L. Jepson, Wheeling		
Wisconsin	J. M. Beffel, Milwaukee	Madison	Jan. 12
Wyoming	J. B. Tyrrell, Laramie	Cheyenne	

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Therapeutic Hints.

An Antipruritic Powder.—The following is recommended by Bulkley as effective in the relief of pruritus:

℞ Camphor, ½ dram.
Zinc oxide, 2 drams.
Starch, 4 drams.

Acute Poisoning by Phenolphthalein.—A. Roux reports the case of a girl 19 years of age who, on the fourth day of the eruptive period of an attack of measles, was given two tablets of phenolphthalein (the dose is not mentioned). A few minutes later she was seized with intense delirium and motor excitement, and then passed into coma. The lips and the nail-beds were of a violaceous color, the pupils were dilated, and the reflexes were abolished. In spite of the hypodermic administration of ether and apomorphine, and the performance of venesection, the patient died forty minutes after having been given the drug. The author attributes the series of events in this case to a condition of anaphylaxis. He cautions one against the use of phenolphthalein in cases of infectious disease in which there may be an impairment of hepatic function.—*La Quinzaine Thérapeutique.*

The Treatment of Asthma.—M. Ségard recommends the administration during the attack of the following:

℞ Theobromine, 0.20 gram.
Valerianate of caffeine, 0.05 gram.

This should be given in a cachet, two to four times a day.—*L'Hôpital.*

Autoserotherapy in Anaphylactic Shock.—Widal, Abrami, and Brissaud studied the conditions under which anaphylactic shock might be made to serve a useful purpose in therapeutics. The increased coagulability of the blood which is one of the manifestations of anaphylaxis may be utilized in the treatment of such conditions as hemophilia. But this increased coagulability is not peculiar to anaphylaxis. It occurs as the result of inoculating a person with his own blood-serum, obtained after allowing a small amount of his blood to coagulate at the temperature of the laboratory. This inoculation is not followed by any untoward symptoms, not even by an urticuria. Moreover it has been found that this autoserotherapy serves to counteract the symptoms of anaphylactic shock such as fever, collapse, and urticaria. The method has also been employed favorably in the treatment of three cases of paroxysmal hemoglobinuria that resulted from surface chilling. Martin and Darré found that by injecting infants with .2 c.c. of their own serum they could in one-third of the cases control the unfavorable manifestations of anaphylaxis.—*Le Bulletin Médical.*

The Treatment of Dysmenorrhea.—S. W. Bandler states that in addition to the use of tonics, hydrastis and viburnum prunifolium may be given for long periods. Apiol, 4 minims in capsules, several times a day, may be begun, a week or ten days before each menstruation. A valuable combination is the following:

℞ Tincture of gelsemium,
Tincture of cannabis indica, āā ℥iii
Compound tincture of cardamoms, ad ℥iii

This should be given in teaspoonful doses four times a day, beginning several days before the onset of menstruation.—"Medical Gynecology."

METCHNIKOFF'S BASIC PRINCIPLE — INTESTINAL ANTISEPSIS THROUGH BIOLOGICAL AIDS—ATTESTED BY THE BACILLUS BULGARICUS.

BY BOND STOW, A.M., M.D.,

NEW YORK.

PRESIDENT ERNEST FOX NICHOLS in a short address on "Ideas" before his students in the Chapel of Dartmouth College on February 9, 1913, among other things said:

"Behind every method, every practice, every custom lies an idea or group of ideas,—a theory,—a reason. Hence behind the practice lies the theory and a full statement of the theory is the rule of the higher practice. Hence the only really practical things in life are ideas; the only practical man, the man of ideas, the man who knows. It is thus to the man of sound theory we must ever look for better ways of doing the world's work."

The world has been enriched by the lives of a few men who bravely and self-sacrificingly have struggled with and conquered great ideas, ideas that have penetrated the local mists of scepticism and cynicism, like beacon lights, because they represented a vital truth. Prof. Elie Metchnikoff, of the Institut Pasteur, Paris, by his struggles for the past quarter of a century has wrested from the hard-fisted grasp of nature a *large idea* which today successfully is withstanding the world's most insistent challenges, just as his now universally accepted phagocytic theory has done since its incipiency.

He has given the world a second great truth. This new theory of the lactic bacillary treatment of many pathological conditions particularly by the *Bacillus bulgaricus* which Professor Metchnikoff so recently has culminated into practical conclusions, under the severe daily tests of practical application, is gaining in trustworthiness and becoming recognized as a vital truth which promises justly to assume front rank among the great gifts of medicine to mankind. How long it will be before this truth is universally put into practice remains to be seen. Sir Edward Grey in a recent address concluded as follows: "It is not difficult to tell the truth; the difficulty is to get the truth believed. It is easy to get something which is not the truth believed. Anybody can do that. It is common to all human nature to prefer to believe that which is exciting rather than what is soothing."

Professor Metchnikoff from his extensive anthropological, bacteriological, and chemical investigations concludes that man's tissues are deprived of their best work and his life actually shortened because of a constant daily poisoning of his vital organs (the liver, pancreas, kidney, etc.) which causes their inefficiency, gradual disintegration, and premature death. Such an intoxication could have no other source than the intestinal tract harboring as it does myriads of proteolytic, anaerobic, indologenous, putrefactive microorganisms.

These bacteria act upon food products especially the proteins, amino-bodies, and the resultants of a faulty metabolism forming toxic products known as indol, phenol, and paracresol compounds, etc., which are continually being reabsorbed into the system causing serious disturbances in the digestive, cardiovascular, nervous, and that entire correllated system of the ductless glands whose normal functions are so essential in preserving an harmonious action of all the organs in the body. These disturbances are grouped together under the general term —*autointoxication*.

Experimental studies from the Institut Pasteur, Paris, have proved conclusively that the premature senile changes induced in animals by the daily feeding to them some one of these indol, phenol, or paracresol compounds are strikingly similar to those pathological changes common to all that occur in the aged; namely, the invasion of the tissues by mononuclears and macrophages, the increased formation of connective tissues, and consecutive atrophy and gradual disappearance of the parenchyma of the vital organs. Thus the two factors active in the formation of these deadly aromatic poisons are diet and the bacteria of the intestinal tract. The control of man's diet is readily accomplished, but mastery over his intestinal bacterial flora is not.

The removal of these hostile microorganisms is spoken of as intestinal antisepsis, for many years one of the chief aims of all therapeutists. The expression "intestinal antisepsis" is here used in a medical sense rather than a strict surgical one since the latter is unattainable. Intestinal antisepsis at all periods of life is a self-evident necessity and particularly so in the very young.

Its accomplishment through drug medication such as purgatives, antiseptics, and germicides, has proved a failure and stands today abandoned by all well-informed, advanced therapeutists. Such measures when used in strength sufficient to act as germicides either cause direct local injury to the intestinal walls or else pervert the natural action of the gastrointestinal ferments. Hence some agency that can overcome these enemies of mankind without injury to the function or tissues of the intestinal walls must be found.

The hopelessness of drug medication to solve this serious problem turned Professor Metchnikoff and his able assistants to biological aids. If the germs of putrefaction cannot be avoided, then the best solution for overcoming them lies in a means of creating constantly conditions in the intestinal tract unfavorable for their growth. His working

formula was: *Malevolent germs must be fought with beneficent ones.* But what microorganisms will prove man's defender and whence the source of these?

Such a question assumes large proportions when one stands and faces it squarely as has Metchnikoff, and it is only from a man of his broad and varied scientific attainments, a veritable student of Life, that the solution of so difficult a problem could be expected. It all seems so simple today, but we who are privileged to enjoy the benefits of his great discovery have little concept of the struggle that wrested the secret out of the great unknown. Metchnikoff's anthropological studies proved most valuable in directing his thought along proper channels for the solution of this problem.

The many notable instances of longevity and the high degree of vitality that exists among the aged in the Eastern countries, where much of their food products are preserved by lactic acid ferments, strongly impressed him. Already years before his renowned predecessor Pasteur, by his epoch-making studies on fermentations, had pointed out the strong antithesis between lactic acid bacilli and the microorganisms causing putrefaction.

Metchnikoff and his assistants at the Institut Pasteur made an exhaustive study of the soured milks so universally used in the Eastern countries and especially of Yahourt, the mainstay of diet of the peasants of Bulgaria, and it was found that the chief agent causing the souring of this milk was a lactic-acid-producing bacillus.

This microorganism is now known as the *Bacillus bulgaricus* and he found it possessed in an eminent degree the following qualifications for this special work of intestinal antisepsis:

(1) It produces the greatest amount of lactic acid of any known lactic-acid-producing microorganism.

(2) It is resistant to external influences so as not easily to be destroyed.

(3) It readily withstands digestion and therefore passes the stomach unharmed.

(4) It will implant itself and readily grow in the intestines, continuing there viable and reproducing itself several weeks after the last ingestion. This latter statement is proved by the scientific investigations of indisputable reliability carried on at the Institut Pasteur, Paris. These experiments were made upon both man and animals and have shown the recovery of the *Bacillus bulgaricus* from the excreta within six to ten days and for several weeks after the last ingestion, from which again pure cultures were obtained.

(5) The *Bacillus bulgaricus* is always nonpathogenic, causing neither general nor local injury to man at any age.

(6) The antagonism of the *Bacillus bulgaricus* to all putrefactive indologenous microorganisms (which demand an alkaline or neutral medium for their development) is twofold: (*a*) it generates nascent lactic acid from sugars and carbohydrates, and (*b*) as Belonowsky of the Pasteur Institute so conclusively has proven, it also produces some form of an enzyme (the exact nature of which is yet to be determined) which also inhibits the growth and destroys the bacteria of putrefaction.

For the above well-named reasons the *Bacillus bulgaricus* that Professor Metchnikoff now recommends (and for good reasons it is best to follow his advice) was selected for this special work of preventing autointoxication which subsequent daily experience proves it most successfully is accomplishing. Thus step by step through long years of study from numerous sources have been forged the links in the chain of evidence that establishes the true theory of intestinal antisepsis, the accomplishment of which is Professor Metchnikoff's basic principle, not so much for prolonging the span of human life (as his conclusions popularly have been misinterpreted), but rather for the maintenance of our nobler tissues in their highest degree of efficiency throughout their natural existence. If such a desired end is accomplished the span of life inevitably must be lengthened.

Keeping uppermost in one's thought this fundamental basic principle it is easy to see how far-reaching in its beneficent results this newly discovered truth must become when universally put into practical use.

Man's natural powers of resistance to infectious diseases, especially tuberculosis, will be enhanced. Tuberculosis cannot be avoided. It is as ubiquitous as blue mold. Some advanced workers in bacteriology even now have strong suspicions that tuberculosis is a streptothrix (distributed everywhere) like unto mold and not a specific entity the same as Loeffler's bacillus is of diphtheria.

The records of the autopsies at Vienna will show as high as 94 per cent. infected with tuberculosis in an active or healed state.

Sir William Osler in his latest London address at a conference on preventing consumption stated: "In 90 per cent. of you would be found somewhere a small area of tuberculosis." What part of that 90 per cent. will be able to resist the disease? What part inevitably must succumb for want of natural protective bodies in their blood with which effectively to overcome the enemy? What part might be saved had they followed Metchnikoff's basic principle: *Intestinal antisepsis* maintained by the daily use of his cultures of the *Bacillus bulgaricus?* These are indeed vital questions. It is useless to try and stamp out tuberculosis. We must teach ourselves to live with it. There is no other treatment for this arch enemy of man than *man himself.* He must maintain in their highest efficiency his blood-making organs creating their defensive agencies. This is accomplished in three ways: (1) Plenty of fresh air and sunshine. (2) Bounteous pure food and drink. (3) Intestinal antisepsis. Metchnikoff has pointed the way how this *third* may be successfully accomplished and has thereby conferred upon mankind one of its greatest blessings.

The average standard of man's capabilities will be considerably higher and the world's work accomplished with greater ease where intestinal antisepsis is maintained. The cleansing of man's inner tissues is of even higher importance than that of his exterior. Both are necessary for the highest efficiency of our human machines.

Man from the beginning has been and ever will be subject to the attacks of these hostile putrefactive bacteria, and the innumerable examples of autointoxication that one sees in his daily walks in life is a proof thereof.

They are the cases that present the sallow, bloodless, or ashy-gray, muddy complexion, foul fecal odorous breath, cold, clammy, moist hands and feet, headaches, malaise, total lack of ambition so that every effort in life is a burden, mental depression often bordering upon melancholia, frequent attacks of indefinite abdominal pains due to flatulency, sud-

den attacks of acute diarrhea alternating with periods of constipation. In others there may be decided attacks of colic accompanied by discharge of mucous shreds and even entire mucous casts from the bowel.

The degrees of these cases of intestinal intoxication vary over a wide range but in *all* intestinal stasis and excessive accumulation of the indologenous putrefactive bacteria in the bowel producing their deadly indols and phenols is the underlying etiological factor. It is this large class of patients for which the physician has advised all forms of purgatives, intestinal antiseptics, tonics, massage, electricity, diet, and finally (as a dernier resort) travel in a foreign land, a *Nirvana* to the physician if not to his poor helpless patient.

Wherein lay his failure? The agencies he employed did not have that hourly punch so requisite to overcome the enemy. They did not strike at the root of the trouble by dispelling a malevolent intestinal flora with a beneficent one. This problem requires an organic force equal and even greater in power than this evil organic one so strongly entrenched in the intestinal tract of every human being.

A battle royal must be fought and when this first great struggle ends in victory for the *Bacillus bulgaricus* it must be kept on the field of battle forever at guard, for the germs of putrefaction are ubiquitous and swallowed with every mouthful of food and drink. If food and drink are essential for the life and growth of human tissues so is some agency that can keep in a healthy state the intestinal tract where that food and drink becomes metabolized, and that agency today Metchnikoff has discovered is the *Bacillus bulgaricus*.

Let us approach a little nearer these combatants, their weapons, and the resultants of this battle for supremacy.

THE BATTLE FOR SUPREMACY.—*Time:*—Past, present, future.

Battle Ground.—Intestinal tract of every human being especially the ileocecal region and ascending colon.

Malevolent Forces.—Bacillus coli, Bacillus proteus, Bacillus welchii (aërogenes capsulatus) (perfringens), Bacillus putrificus coli, Bacillus subtilis, Bacillus sporogenes, Bacillus cloacæ, staphylococci, streptococci, others undetermined.

Essentials for Life and Growth.—(1) Alkaline or neutral medium.

(2) *Food Products.*—(*a*) Proteins, (*b*) aminobodies, (*c*) resultants of a faulty metabolism.

Weapons of Offense (generated in loco).—Indol and phenol (most dangerous, Metchnikoff), paracresol, skatol, aromatic oxacids, hexone bodies, mercaptan, hydrogen sulphide, ptomains, toxalbumins.

Resultants of Attack.—A daily insidious poisoning of the nobler parenchymatous tissues of our vital organs together with an interference with the normal correlations of the internal secretions of the ductless glands (pituitary, thyroid, adrenal, etc.) which regulate the proper functioning of the nervous, circulatory, digestive, and eliminative organs.

Ultimate End Resultant. — Increased arterial pressure accompanied by a gradual degeneration and sclerosis of the arterioles with an increasing growth of the connective tissues and a diminution by pressure atrophy of the parenchymatous tissues ending in their premature decay and death.

Beneficent Forces.—Bacillus bulgaricus, other lactic acid bacteria.

Weapons of Defense (generated in loco).—(1) Nascent lactic acid generated from (*a*) sugars, (*b*) other carbohydrates; (2) An enzyme (yet definitely to be determined) produced from the body of the *Bacillus bulgaricus* (Belonowsky).

Chief Characteristics.—(1) A large (5-50 microns) gram-positive, nonsporogenous bacillus. (2) Forms the largest amount of nascent lactic acid of any known microorganism. (3) The formation of peculiar node-like bodies during the development of the bacillus is its distinguishing morphological feature. The destiny and purpose of these nodes is as yet undetermined. (4) Will not grow in plain bouillon or on agar. (5) Produces no appreciable quantity of alcohol, succinic acid, or acetone. (6) Readily survives digestion and admits of easy implantation upon the intestinal tract of man at any age (30 to 36 hours after ingestion). (7) Remains viable practically for four to six weeks after last ingestion. (8) Causes neither local nor general injury to the tissues. (9) It aids in the assimilation of food products by stimulating the organs of digestion, especially the bile and pancreatic secretions.

Reinforcements.—The *Bacillus bulgaricus* gradually becomes attenuated and dies out if not reinforced, owing to the large numbers of malevolent microorganisms daily ingested with our raw foods and drinkables. An entire reimplantation or else a continuation of the implantation already secured is necessary on this account.

Duration of this Battle.—Malevolent microorganisms are ubiquitous and unavoidable, hence this battle never ceases.

To-day intestinal antisepsis is accomplished with much assurance of success by cultures of the *Bacillus bulgaricus*. But what cultures of this bacillus?

Surely not any old culture much attenuated or practically dead and of low bacterial count. The practitioner must exercise much discretion in the choice of the product he employs. He must convince himself that the cultures he employs are pure, fresh, viable and of highest possible bacterial count. He should acquaint himself with the bacteriologist and laboratory that furnish him his cultures. He should always bear in mind—*This is bacteriotherapy*, and failure to obtain the results looked for are more often due to the inefficient weapons he is employing than the principle involved. Persistent daily use of proper cultures (such as recommended by Professor Metchnikoff) taken before meals and at bedtime, when combined with well-directed dietetic measures, will accomplish more to overcome autointoxication with its direful end resultants than any other line of treatment heretofore attempted, not excepting even in severe types the latest proposed surgical procedure, ileocolostomy as practised by Arbuthnot Lane of London.

The brilliant results of ileocolostomy for cases of intestinal stasis when accompanied by a high degree of toxemia, as performed by Lane, clearly demonstrate Metchnikoff's theory of intestinal autointoxication. But it must be borne in mind this is a very severe surgical procedure and excepting in cases of serious organic obstructive lesions should not be advised until a most thorough and exhaustive trial of the *Bacillus bulgaricus* has been undertaken.

A proper intestinal antisepsis maintained under the lactic bacillary treatment will reduce to a very small percentage the necessity for this dangerous surgical procedure.

Free drainage is a fundamental principle for the

successful issue of a surgical case. Free ileal-drainage is a *sine qua non* for the successful permanent implantation of the *Bacillus bulgaricus*. Just as a field must be cleared and ploughed before planting the seed so must the intestinal tract be made ready for the proper reception of the *Bulgarian bacillus*.

The choice of an eliminant is of no small importance. One must constantly bear in mind he is dealing with a viable microorganism which drug medication may destroy or attenuate.

Naturally then such a purgative as calomel cannot be used. The principle to be observed is that form of an eliminant which will aid the intestinal walls in their natural functions without interfering with the powers of the *Bacillus bulgaricus*. Epsom salts combined with lemon juice or some mild aperient water as the Carlsbad Sprudel salts taken with hot water before breakfast naturally suggest themselves in contradistinction to the strong drastic purgatives. And as early as possible even these simpler eliminants should be abandoned in favor of dietetic measures that induce normal intestinal peristalsis such as stewed prunes and figs (half and half) for breakfast, plenty of fresh fruits and green vegetables with much fibrous residue, and bran biscuits made of molasses and bran flour.

Babies are sacrificed in large numbers to the attacks of these hostile putrefactive microorganisms especially during the heated term of the year, and if physicians and mothers will work together harmoniously in the employment of young, fresh, viable cultures of the *Bacillus bulgaricus* the large majority of these fatalities will be checked.

There is no class of cases where more brilliant successes have been accomplished than in these severe cases of summer diarrheas of infants. The Bulgarian bacillus when rightly employed in these cases works with remarkable rapidity and certainty, and it almost seems a public duty that a knowledge of this specific agent and the manner of employing the same should be cast widespread for the saving of these young imperiled lives. Cultures of the *Bacillus bulgaricus* for infants should be grown in a medium particularly adapted to the conditions of the gastrointestinal tract of young infants. This medium must be a readily assimilable form of food closely resembling the natural nourishment of a young suckling infant. Actual practice demonstrates the need of such an infant culture (devoid of the beef and veal peptones universally found in the ordinary cultures) so as to supply proper nourishment and the *Bacillus bulgaricus* at one and the same time.

If the largest percentage of infant troubles during the heated term of the year is due to derangement of the gastrointestinal tract caused by putrefactive and other microorganisms, then it is easily discernible how the proper employment of *such* infant cultures is the agent *par excellence* with which to combat these pathological conditions. In mild cases of infant diarrheas accompanied by frequent stools, green or otherwise, the use of two or three culture tubes daily taken direct from the tube will suffice within a few days to restore the gastrointestinal tract to its normal conditions. Naturally the usual hygienic measures with reference to cleanliness, sterile implements employed in its feeding, and proper dietary directions must coexistently be employed.

In the severer cases, where extreme emaciation and very numerous stools are present and time is a most urgent factor in establishing in the bowel at the earliest possible moment, a culture of the Bulgarian bacillus, a much more vigorous attack must be made. Here it is advisable to place the contents of two to four tubes in about two ounces of warm water (100° F.) and inject the same high up to the splenic junction of the colon both night and morning. These injections should be made very slowly, the object being to have the solution retained so as to flood the entire colon with the bacillus. At the same time one tube should be given by the mouth as frequently as every two hours for the first twenty-four hours, bearing in mind that the medium of properly constituted infant cultures is a natural food-product of itself. As the symptoms show amelioration the injections should be given at night only and the doses by mouth reduced to once every six hours. After a few days, all injections should cease and one tube given by mouth night and morning. This line of treatment is almost a specific and has been followed by a speedy return of the stools to normal color, odor, and consistency with increase in weight of the child and marked improvement in its blood and general health.

The principle involved here is the same as in the treatment of all intestinal derangements with the *Bacillus bulgaricus*, we are replacing malevolent death impelling microorganisms with beneficent health restoring ones.

The writer's practical studies for many years at the autopsy table and microscope confirms the conclusion,—There is no one biological principle that more deeply concerns the health and longevity of man and of which he stands more in need than *Intestinal Antisepsis*.

Those who daily follow Professor Metchnikoff in this principle with the cultures he himself employs to consummate it will experience the highest efficiency of their tissues. It is not probable that a man of his versatile scientific training, after a quarter of a century of extensive research work on this all-important subject (himself for many years a daily user of the *Bacillus bulgaricus*), has fallen into error. It has rightly been said of him: "He is seventy years young."

200 West Seventieth Street.

ACUTE CONTAGIOUS CONJUNCTIVITIS.

PRELIMINARY REPORT OF A SERIES OF CASES ORIGINATING IN A PUBLIC SWIMMING POOL.

By SAMUEL HORTON BROWN, M.D.,

PHILADELPHIA.

In the larger cities of the United States it is no uncommon occurrence in the summer months to encounter cases of acute conjunctivitis in youngsters who have been patronizing the public swimming pools. Many attribute this to the mechanical irritation of the water and kindred factors. In the early part of August, 1913, the eye clinics of the central and southern part of Philadelphia (the older part of the city) began to be crowded with a distinct type of conjunctivitis, appearing in epidemic form, and readily traced to a public swimming pool operated by the city of Philadelphia at Third and Queen streets. The infection spread rapidly among the children of the neighborhood, mostly of foreign parents, attacking girls as well as boys, and frequently the eyes of the parents were affected and work was out of question.

By the time the opening of the fall school term began the cases were so numerous that the medical

inspectors were cautioned to be on the alert for cases in the early stages, as well as frank cases, to prevent infection of the entire school population. By means of the services of the school nurses and social workers it was possible to follow up the cases, in order to see that they reported for treatment, and also that new cases in the homes of the patients, or those of their neighbors might be unearthed and promptly treated. This resulted primarily in an increase in the number of cases, as would be expected, and ultimately in a shortening of the course of the disease, and the elimination of foci of infection. By Thanksgiving the condition was no longer an epidemic, but scattered cases were encountered from time to time.

It was my privilege to see the majority of these cases in the eye clinic at the Pennsylvania Hospital, and I take this opportunity to express my appreciation of this privilege of studying them to Dr. Peter N. K. Schwenk and Dr. Wm. T. Shoemaker, ophthalmologists to the hospital.

Our entire experience with the condition covered about 500 cases, of which we were able to follow in detail 314 cases. Of these 24 occurred in persons over 25 years of age, 12 in patients between 15 and 25 years, 90 in individuals over 10 years and under 15 years of age, and 188 in children under 10 years. Of this number 235 were males, mostly boys who had patronized the Third and Queen streets pool, and 79 were females. Sixty-four per cent. of the females were infected after the public schools opened. The school girls were practically free until the school term opened, when all the pre-existing cases were brought together to infect a virgin field.

Nothing pleases the average faultfinder so much as to learn that a school, or a swimming pool, or a bath, or a railroad car, or some other public utility is a source of infection. Nothing is so cheerful to such a person. The fact that it is the faulty management of the same that is the cause, not the utility itself, escapes the critic entirely. Most of these individuals are good, straight-laced people, and they would be shocked beyond description by an assertion that Sunday schools spread more infection than any other aggregations. Who ever heard of fumigating a Sunday school?

It must be borne in mind that most of the public swimming pools in the larger cities are located where they are most needed, and not where they would be most ornamental. Consequently many of the patrons are far from cleanly when they come to the pools and bring with them, unconsciously, the infections theat surround them at home.

Analyzing the sources of contagion, we found that the swimming pool at Third and Queen streets was directly responsible for 85 of our cases, and indirectly responsible for nearly all of them. The public bath at Eighth and Catharine streets was accredited with one case. Six weeks after the epidemic character of the condition was noted there were 7 cases traceable to the Ninth and Montrose streets bath. Three weeks earlier 14 cases were seen from the Eighth and Lombard streets bath. During the fourth week of the epidemic 3 cases were seen that were contracted at Eighth and Mifflin streets pool. One case was observed from the bath at Fourth and Gaskill streets. A private bathhouse at Third and Vine streets contributed 2 cases, and a public bath at Fifth and Fitzwater streets one case to our series.

After the factor of the public bathing pools was recognized by the health authorities appropriate measures were taken to prevent other cases from arising from these sources. The disease did not subside immediately with these measures. Thus 64 cases were noted as coming from houses in which there were other cases, although these 64 patients had not patronized any swimming pool. When school opened, September 9, 1913, new cases were still observed, 89 of which were contracted from other cases in the same neighborhood, and not otherwise noted. At the same time 11 cases were observed in our clinic as occurring apparently sporadically in remote sections of the city. One case appeared incidentally, perhaps, in the course of hay fever, and one in the course of pertussis. Thirty-four of our cases failed to admit of a proper classification as to their sources of contagion, but as they came from the same neighborhood and schools as the majority of our patients, it is reasonable to assume a common source for all of them.

The distribution of these cases on the opening of the school term is interesting, showing the possibilities for the dissemination of any infectious disease. The following schools were accredited in our clinic with the number of cases given, but a census of all the dispensaries and hospitals downtown would show a greater number than we have recorded here. From one school alone we are informed by the nurse in attendance, 60 cases were observed. This was the Henry Burk School at Third and Christian streets. Our record, however, shows but fifteen from this school. The James Campbell School, at Eighth and Fitzwater streets gave us 13 cases. The George Washington School, on Fifth street, below Washington avenue, furnished 6 cases; the Hawthorne School, at Twelfth and Fitzwater streets also gave 6 cases; the Randall School, at Ninth and Bainbridge streets, had four of our cases; the Meredith School, at Fifth and Fitzwater streets, had 4 cases; the Beck School and Florence Annex, at Seventh and Catharine streets, registered 6 cases with us; the Mt. Vernon School, at Third and Catharine streets, registered 4 of our patients; the Binney School, at Sixth and Spruce streets, sent us but 3 cases; the St. Paul's Parochial School, at Seventh and Christian streets, furnished 3 cases; the George M. Wharton School, at Third and Pine streets, sent us 2 cases, and the McCall School, at Sixth and Delancey streets, 3 cases. Two cases each were recorded as coming from the Forten School, Sixth street, above Lombard Street; the Richard Henry Lee School, Front and Christian Streets; the Nebinger School, Sixth street, above Carpenter street, and the John Hay School, on Wharton street, near Sixth street. One case each was observed from each of the following schools; Willard School, Emerald and Orleans streets; Weccacoe School, Second and Reed streets; St. Philip's Parochial School, Second and Christian streets; Fourth and Christian streets School; Fletcher (R. H. Lee) School, Front and Christian streets; Sacred Heart Parochial School, Ralston School, American and Bainbridge streets; Christopher Columbus School, Ninth and Carpenter streets; Columbus Annex, and Our Lady of Good Counsel, Fifth and Carpenter streets.

To any one at all familiar with the geography and topography of Philadelphia it will readily appear that the distribution of this infection was over a comparatively restricted area and among communities in constant communication with each other. This foreign section does not intermingle with other sections of the city to any great extent. We repeat

and beg for allowance for the fact that our cases show only the tendencies of the dissemination, and do not cover the total number of cases occurring in the schools. Before the schools opened it was with the greatest difficulty that we were able to determine the school attended by any particular patient; either the children forgot or didn't know.

Among those whom we can regard as adults—namely, those over fifteen years of age, since these individuals for the most part assume the same economic responsibilities, the possibility of dissemination and the field invaded are of interest. Thus, 13 were mothers, practically heads of households; 8 were general utility men, 1 worked as a barber, 1 in a cigar store, 1 as a tailor, 2 in a trunk factory, 1 in a foundry, 1 in a bottle factory, 1 in a paper box factory, 3 went to school, 1 was a baker, 1 worked as a laborer in a stone yard, 1 was a stone cutter, 1 was a clerk in a lodging house—a total of 36. Twenty-nine of these contracted the disease from children, 4 from adults, and 3 directly from the swimming pools and baths. Evidently the disease does not thrive in the adult and the virus is thereby attenuated. As far as our experience went, the infection spread from the children to the elders and there exhausted itself, since there were very few cases in children or adults that had been contracted from adults.

The extent of the dissemination may be appreciated by the figures submitted by the Social Service Department. Thus in 52 instances each case had infected one other person; in 8 instances 2 persons each were infected; in 8 cases, 3 each; in six cases, 4 each; in two cases, 5 each, and in one instance 7 were infected. These were direct cases of infection. In some instances the infection was light and no other cases followed, although all conditions seemed conducive to it. Thus only one case was observed in two households of eleven people, two households of eight people, one of seven people, and two of five people, in a lodging house where the clerk and manager was infected.

The duration of the disease in individual cases was greatly influenced by treatment and by the discovery of latent or rather untreated cases. The Social Service Department, when informed of the presence of a fresh case, usually produced within a day or two one or more cases from the same house or neighborhood of two weeks or more duration. Thus the cases referred from this department to the clinic showed a variation in duration of the disease prior to being observed by us, as follows:

One case, 12 hours; 24 cases, 1 day; 19 cases, 2 days; 70 cases, 3 days; 19 cases, 4 days; 5 cases, 11 days; 1 case, 6 days; 26 cases, 1 week; 14 cases, 2 weeks; 8 cases, 3 weeks; 4 cases, 4 weeks; 1 case, 5 weeks; 4 cases, 2 months; 1 case, 3 months. The cases that consulted us independently of any Social Service showed the following duration prior to our observations:

Two cases, 12 hours; 11 cases, 1 day; 11 cases, 2 days; 19 cases, 3 days; 11 cases, 4 days; 11 cases, 5 days; 6 cases, 1 week; 2 cases, 2 weeks; 1 case, 4 weeks; 37 cases, indefinite. Thus it will be noted that the cases seemed to occur in pairs, two or three days with ten days or two weeks. When the disease began as a monocular condition, however, the fellow eye was infected in twelve to twenty-four hours, which period must, therefore, be assumed as the correct incubation period.

The clinical appearance presented by the patients upon their first visit to the hospital is rather interesting. Thus in 314 cases the bulbar conjunctiva was so intensely congested as to justify the popular designation of "pink eye." The palpebral conjunctiva was the subject of pronounced congestion in but 38 cases and pronounced swelling of the lids was present in but 36 cases. Of much greater frequency was edema of the conjunctiva or chemosis, which was observed in 216 cases out of the series of 314. The bulbar congestion frequently gave the appearance of impending subconjunctival hemorrhage, but a frank hemorrhagic appearance was noted in but 16 cases, and these were in adults. Profuse discharge was observed in 270 cases, although without our records we would have said profuse mucopurulent discharge was a characteristic of the entire series of 314 cases.

Among the subjective symptoms, an inability to use the eyes, was a prominent complaint in 250 instances, and it is this fact that has justified the study of this disease in this particular instance. Any disease or condition that interferes with efficiency, becomes of economic importance. If we determine the aggregate period of disability in this series and multiply it by the average daily wage we readily appreciate the economic loss this disease has caused the community, independent of the time and money expended in an effort to combat and relieve the conjunctivitis.

Pain, itching, and burning were present in 4 cases, all adults; photophobia occurred in 6 adults. There were practically no other subjective symptoms except those incidental to the discharge.

As the disease progressed complications ensued, and perhaps the earliest noted were phlyctenules, which appeared within the first week in 18 cases. When the cases were of long standing the lymphatic follicles in the lower lid enlarged to a noticeable degree in 26 cases, and to a most pronounced degree, resembling trachoma, in 20 cases. Other complications were: Blepharitis, 1 case; herpes simplex of conjunctiva, cornea and eyelids, 1 case; hay fever, 1 case; pertussis, 1 case; episcleritis, 1 case; hordeolum, 1 case; pediculosis ciliarum, 1 case; corneal ulcer, 1 case; facial palsy, 1 case; orbital cellulitis, 1 case; superficial keratitis, 1 case; pterygium, 1 case; macula corneæ, 1 case; remote anterior adherent leucoma, 1 case. These may be taken as largely incidental. Trachoma was present in 4 cases and nasal discharge in 3 cases.

Among the complications it was noteworthy that only one corneal ulcer was observed, and it was probably only an incident and not due to the infection. This will bear out the contention that corneal ulcers seen in all conjunctival inflammations (especially ophthalmia neonatorum and purulent conjunctivitis) are due to injury and direct infection of the cornea and are not caused by swelling of the conjunctiva shutting off the nutrition of the cornea. A healthy cornea with an unabraded epithelial surface, is, in our belief, unlikely to be the seat of ulceration, even when the conjunctival inflammation is most severe and intense.

The enlarged follicles and granulation in both cul-de-sacs suggests an explanation of the great number of cases of trachoma, so-called, seen in some communities. There is no question that follicular enlargements are a terminal stage of most prolonged conjunctival inflammations. With the exception of four of our cases, all underwent involution, but the persistence of these four warranted us in assuming that they were cases of trachoma prior to the Koch-Weeks infection.

At the beginning of the epidemic efforts were made to study the condition from a bacteriological standpoint. Smears and cover glass preparation were made routinely in 26 cases, with the result that gram positive bacteria were found in 1 case, mucus in 3 cases and Koch-Weeks bacilli in 6 cases. It was very evident from this that something was wrong with our technique or else the laboratory men were unusually conscientious and refused to find for us the particular kind of bacteria we had ordered. The entire bacteriology of the cases was then placed in the hands of the laboratory men and fifteen cultures were made. Loeffler's blood serum tubes were inoculated and a pure growth of Koch-Weeks bacillus found in seven instances and the Xerosis bacillus in 4 cases. Staphyloccoci were found in the smears previously noted, but as the investigation was directed against a definite microorganism no mention was made of them.

It is very obvious, then, that our bacteriological investigations were not a huge success. After the third week of the epidemic we were so crowded in the clinic with work that further special work was impossible. We have proceeded, however, to study the natural history of the Koch-Weeks bacillus obtained in the cultures, and this is not completed, hence the term "preliminary" in the title of this paper.

While the bacteriological features of this epidemic were unsatisfactory, there were other features which were highly gratifying. For instance, there were 195 patients who failed to return after the first visit. For all practical purposes they were cured very shortly, because—in the case of school children, which most of them were—the school was notified and the child compelled to seek treatment somewhere—if not at our clinic, at some other one. In any event social workers visited the homes of the patients and determined why the patients did not return. Nearly all of them did not return at the time specified (four days) because they were well enough not to require to do so, they thought.

A number of school children (forty-nine) were infected in the early part of the summer who did not come under the supervision of the school nurses or Social Service in the early stages, but who straggled along in their attendance at the clinic and carried the disease for practically six weeks. At the end of this period the schools opened, and these children were "socialized" and involution of the disease was prompt.

The duration of the disease in other instances, after treatment was instituted, is of interest. Thus in 8 cases the disease lasted 4 days; in 12 cases, 7 days; in 1 case, 9 days; in 9 cases, 11 days; in 5 cases, 13 days; in 5 cases, 14 days; in 3 cases, 16 days; in 4 cases, 18 days; in 3 cases, 19 days; in 4 cases, 20 days; in 4 cases, 22 days; in 1 case 24 days; in 4 cases, 30 days; in 1 case, 5 weeks; in 1 case, 6 weeks; in 1 case, 2 months; in 4 cases, 3 months. Comparing this with the duration of the disease in the untreated cases the difference is remarkable. The duration of the cases that were detected by the social worker and those occurring in patients who voluntarily came to the clinic has already been given.

Each patient was placed upon a routine treatment at the very beginning of the treatment, consisting of iced compresses, boric acid solution (boric acid gr. x, sodium biborate gr. i, distilled water, 1 ounce) every hour, and the instillation twice or three times daily, of one drop of a solution of toluidin blue (1 to 1,000) at the suggestion of Dr. C. P. Franklin. The patient was instructed to return on alternate days to the clinic and the application of a 2 gr. to the ounce silver solution was made. At first treatment was directed only toward the affected eye, but shortly it was deemed advisable to treat both eyes from the very beginning. The duration in the latter was much shorter than in the former cases. As follicular enlargements and granulations made their appearance, boroglycerin, (50 per cent. in glycerin, not water), at the suggestion of Dr. Conrad Berens or glycerole of tannin (10 per cent.) was applied. At the suggestion of Dr. P. N. K. Schwenk, the chief of the clinic, the following preparation—boric acid, gr. xxv, sodium biborate, gr. x, distilled water, 1 ounce—was used in ten cases. The increase in the quantity of sodium biborate to the ounce permits the perfect solution of a greater quantity of boric acid than usually employed. In 55 cases the ordinary boric acid solution (gr. x to the ounce) was employed. In drawing comparisons between these three methods, it would appear that each was equally serviceable in the cases in which it was employed. In 200 cases in which boric acid and toluidin blue were used 61 failed to return after two or three visits, and, we assume, were promptly relieved. The greatest factor in whatever treatment used is the persistent use of it. The instillation of clean, cold water every hour in these cases, we have no doubt, would have been equally efficient; thus it is we find good results from all of the treatments, because through the aid of the Social Service, the treatment was actually employed and not used in the customary desultory way. As regards antisepticizing the conjunctiva, we believe nothing accomplishes that so well as a weak solution of nitrate of silver.

From this survey of 314 cases of acute contagious conjunctivitis, occurring more or less simultaneously, and in a manner constituting an epidemic, we conclude that the causal agent is more likely to be encountered in the public swimming pool than elsewhere, due to the unsanitary regulations governing such institutions. The difficulty with which specific bacilli are cultivated, even from soiled handkerchiefs and towels, places the responsibility directly on the stagnant water of the public pools. We have directly infected pieces of handkerchiefs and towels and the bacilli died of inanition on them, in so far as we are able to determine at this writing. We further conclude that the conjunctival cul-de-sacs of children provide the factors for the growth of the disease better than adults. In adults the virus, or whatever it may be called, became very much attenuated and failed to produce the disease in other adults, except in very few cases, and not at all in other children. Another conclusion we are inclined to reiterate is that severe inflammation with intense swelling, edema and chemosis of the lids and conjunctiva will not produce corneal ulceration if the corneal epithelium be not abraded either by the patient or rough handling by the doctor. That any form of conjunctival inflammation may follow infection of this character is also proved by the occurrence of the several different kinds of complications and sequels. The occurrence of a simple form of granular conjunctivitis, really exuberant granulation tissue unassociated with trachoma and unattached by its complications or sequels, is likewise amply proved by the observations of this series of cases. The value of persistent treatment is again demonstrated and the efficiency of the

Social Service Department is brought out very prominently.

The argument advanced to justify the existence of the Social Service in the hospital is that the follow-up work enables the physician to obtain results from his treatment. This is amply shown by our observation and confirmed by the following report of Mrs. Martha J. Megee, head of the Pennsylvania Hospital Social Service Department:

"The Social Service finds, in perusing its records, a total number of 754 cases of acute contagious conjunctivitis under observation in the eye clinics of the Pennsylvania Hospital from May 1, 1913, to February 28, 1914. Of this number over 200 were referred to the department for investigation, and the several other purposes for which such departments are instituted and organized. The investigators were impressed with the necessity of determining how many other infected individuals were in the family, how many were in the same house, and how many were in the immediate neighborhood. It was then determined whether these cases were under treatment and where; if not under treatment, they were advised to go to some physician or clinic immediately, and encouraged to seek relief at the Pennsylvania Hospital Out-Patient Department. In the case of school children, the school they attended was determined and notified of the existing condition; when these children came to the hospital, the cooperation between the clinics, the Social Service, the school supervisors and associates, and the school physicians and nurses, was such that the course of the disease was carefully observed in all of its features, medical, sociological, etc., to the great advantage of the children and the public with which they came in contact.

"At the beginning of the pronounced epidemic originating, as we subsequently proved, at the public swimming pool at Third and Queen streets, the workers investigated conditions at the pool on more than one occasion and satisfied themselves that the heads of the appropriate departments in City Hall had no immediate knowledge of conditions as they then existed. Similar conditions probably existed in the other pools throughout the city, but of this we have no personal knowledge. City Hall was notified through several sources and attempts were made to ameliorate conditions.

"In the investigating of the home conditions our workers readily appreciated the features of the disease as explained by the physicians in charge of the patients, and it was with little difficulty that they impressed upon the parents of the children the need of a physician's care immediately, the necessity of regular attendance at the clinic and regularity in applying the treatment (often making the treatments themselves or explaining how they should be made in the home), the prime importance of cleanliness, and the means of preventing infection of other people.

"Later, when school opened, the cooperation of the school attachés enabled us to have the children excused and kept from school pending involution of the disease; these children were then followed up and their attendance at the clinic checked up. An absentee was reported to the school and advised to return to the clinic at the appointed time. Failure resulted in notification of the Bureau of Compulsory Education. Children were readmitted to school when discharged by the clinic staff, and the Social Service advised the school supervisor. This courtesy was extended by the school physicians."

The statistics of the cases show some very interesting facts. Thus, from May 1 to July 30 there were 46 cases; from July 30 to September 30 these increased to 405 cases; from September 30 to December 30 the number fell to 221; from December 30 to February 2, 1914, there were only 82 cases. This entailed over 600 visits on the part of the Social Service Department's workers. When it is remembered that for this period of ten months these cases constituted 23 per cent. of the new cases seen in the eye clinics, and that during August and September the percentage jumped to 40, it will be readily seen that this work on the part of the Social Service Department was justifiable and necessary.

The lessons learned through this experience have been placed before the new Director of Public Health, Dr. Richard Harte, formerly a member of the staff of Pennsylvania Hospital, and the prospects are very bright for the prevention of such an epidemic during the rapidly approaching summer of 1914.

1901 Mt. Vernon Street.

ASPECTS OF VISUAL ACUITY.

By HENRY M. FRIEDMAN, M.D., LL.M.,

NEW YORK,

ACTING ASSISTANT SURGEON, UNITED STATES PUCLIC HEALTH SERVICE.

There is probably no other factor quite so important to the enjoyment and usefulness of the human economy as vision. It is the avenue through which the major portion of the stimuli from the outside reach our minds. It is the visual concept which rises in importance directly as there is a rise in our civilization. Civilization means visualization. The visual concept is a most important one in modern methods of education. Now, even the deaf can be made to "hear" through their visual sense, and in this respect the visual sense becomes a combination of the senses of hearing and vision. The higher becomes our plane of civilization the greater call is there made on the visual sense, and the greater is the requirement for an unimpaired vision. This is now everywhere realized, and has resulted in organized attempts at conservation, at least from such tangibly preventable causes as infantile and adult gonorrhea, industrial injuries, etc. Good results of this crusade are already manifesting themselves.

Little attention has thus far, however, been paid to the conservation of visual acuity. Consistent medical inspection of school children demonstrates the large percentage of visual defects among them. In the larger centers efforts at correction and the prevention of further development have been tried. It is important to obtain and to retain for each individual the maximum amount of visual acuity possible. The average range of human vision does not vary much, and if only for uniformity's sake all vision should correspond to that average. The reason for the presence of vision below or above this average is given by some investigators as caused by heredity or hereditary predisposition; by others, as being characteristics entirely acquired. The question is far from being a settled one. From the standpoint of prevention of the development of acuovisual defects, it is probably better to ignore the heredity theory, and accept the acquired theory. The general impression, however, is that several characteristics in the visual complex are concerned in acuovisual defects, and are transmitted merely

as hereditary predispositions. There is a tendency to deny heredity in the nearsighted—the myopes, —and to concede the possibility in the farsighted—the hypermetropes. It is estimated that not more than 10 per cent. of visual defects are hereditary and that the majority of these are the farsighted. Myopia is attributed to one form or another of unhygienic optics, thus making the condition entirely preventable. On the other hand the Galton laboratories found no predominance of visual defects among the overcrowded or the unhygienic. In fact the actual statistics adduced showed better vision among the poor and the unhealthy than among the better classes. Their results showed that health and environment bore no relation to visual acuity. But whatever these investigations show, the fact remains, that there is a large field for prevention in optics, so to speak, which needs to be developed.

In speaking of visual acuity the distance at which an object is distinctly visible, is usually meant. According to this nomenclature the farsighted would have acute vision, and the nearsighted ones subacute. This conception is not entirely correct, since at a certain focal point the myope's vision is just as acute as the hypermetrope's, but in the former that point is much nearer to the eye than in the latter. The myope's acute vision is therefore at a near point, the hypermetrope's at a more distant point. In grading the visual acuity of a myope at half because he sees the standard test type only at half the distance, you do him an injustice, unless, indeed, you qualify the statement properly; since his vision at half the distance is just as acute as the normal's at twice the distance—or some such ratio. On the other hand, a myopic eye can see twice as near, so to speak, as the normal eye, yet the normal eye has not therefore half the vision. The very acute vision at a near point, together with the magnification of objects which the myope possesses, is a decided advantage to him, especially in certain occupations requiring close application. Whether this advantage overcomes the undoubted disadvantage of the restriction of the distant range of vision, is an open question. Clinically, a myope is defective for distant vision, and a hypermetrope for near vision. For the sake of accuracy and to prevent confusion, especially in the communication of these defects to laymen, it is important to specify the type and degree of the defect.

From the standpoint of actual acuity of vision, it is perhaps more proper to say that one has not acute vision who at no distance sees an object clearly or has the image sharply defined. While this may be due to purely refractive errors uncorrected, like astigmatism, in which owing to differences in or asymmetry of the corneal curvature, vision is clear at no point, it is more nearly true in such pathological conditions as are found in diseases of the various media of the eye, the retina, the choroid, optic nerve, or even the cerebral endings. In these conditions there is diminution for both distance and acuity, and lenses can have no correcting influence.

The range of vision in an individual varies between his near and far points, and the regulation of these distances is accomplished through the accomodative apparatus. In young children the power of accommodation is very well developed, even to a maximum of fourteen diopters. A diopter is the unit of refractive power, and expresses the power of a lens whose focal distance is one meter; the higher the dioptric index of the lens, the shorter the focal distance. High power lenses have, therefore, a shorter focal length, and vice versa. The large range and amplitude of accommodation of children, which becomes less as the child grows older, and is slight in adults, frequently masks acuovisual defects. These may not be discovered till later in life, when the damage from the uncorrected refractive error can be but little remedied. For this reason a routine examination of children of school age, perhaps even with a cycloplegic to paralyze accommodation, might not be amiss, in order to determine the presence of possible error, and then to correct it. While complicated refractive errors require the services of trained opthalmologists, the general practitioner should at least be able to determine the presence of the defects, and in the simpler cases to correct them.

For determining the acuity of vision, especially for record purposes, a test type card modified after the principle of the Snellen card, is employed. The test type are letters so arranged that they decrease in size from above downward. The largest letter at the top should be read at 200 feet, the letters on the next line at 100 feet, and so on down to letters so small that they should be read at 20 feet, at 15 feet, and even at 10 feet. Standard vision sees the various sized letters at the designated distances, but for record purposes especially, the 20-foot type at 20 feet. This standard is designated as 20/20 vision. The numerator of this fraction is the fixed number 20, representing the distance at which the patient stands from the test card, the denominator varies according to the size of the letters he sees at this distance. The test type itself is a visual angle of 5′ subtended by the letters, or 1′ subtended by each of the component lines.

A little too much reliance is perhaps placed on the test type as an indicator of visual acuity in civil, commercial, and military examinations. Certain conditions affect this test, and should be borne in mind. The Snellen standard does not represent the average acuity, nor does it represent the maximum acuity. Neither is the result of this test an index of what the eye can do when put to practical test. For this reason the test card characters and the test in general should conform as far as possible to conditions under which the eyes are generally used. For it is a significant fact with how little really acute vision one can get along, and with how much less distant vision. Nearly in every walk of life, except in those occupations in which the very nature of the work requires the maximum amount of distant vision, one sees individuals who get along on a fractional part of the standard vision.

Factors which influence the result of the test type vision determinations are, principally, illumination, familiarity with letters, and the form of the letters themselves: that is, certain letters, as I and L are more legible than others. Enormous differences in visual acuity are found with the decrease in the illumination intensity, but so far no law of correlation for those differences has been formulated. Yet while illumination of the test type will improve the result, an illumination beyond a reasonable amount will have no effect in this respect. Unless, however, some uniformity in illumination intensity is observed, especially where the question of distant vision is important, results will always vary. One individual may pass a test, whereas another with the same visual acuity may fail simply because the illumination intensity has

varied. Individuals of the same visual acuity will be given different ratings, or individuals with different amounts of visual acuity will be given similar ratings. Artificial illumination, because its intensity can be kept uniform, is the best means of illumination. An eight to ten meter candle light is taken as the equal of 75 per cent. daylight. For the purposes of illumination eight meter candle light is considered a low illumination, while a forty meter candle light is very high for ordinary purposes in respect to uncolored illumination. White illumination gives the most acute vision, then red, then green, then blue. The light question is yet an open one with respect to these determinations, but it should not, therefore, be entirely ignored.

The material question of importance in the matter of visual acuity is the question of the fitness of the individual whose vision, thus in a very approximate way, to be sure, has just been determined for the various occupations of life, and the ability for success in such occupations—the ability of the individual to support himself. Certain occupations require a maximum amount of vision, and preferably a maximum without the correcting influence of glasses. This acuity of vision refers here, of course, to distant vision. Other, and most occupations, do very well with a vision corrected to normal. Still others get along with a visual acuity in varying distances below the standard. In the occupations where distant vision is so important, as in the transportation occupations, testing for distant vision alone is not sufficient, for there may be in young adults a tendency to latent hypermetropia, which when it becomes patent in later years may very materially reduce the vision, and which may or may not be then correctable with lenses. A slight myopia in adults while there is some possibility of increase, is very slight at best. Usually the slight myopia of adults has a tendency to disappear as it is neutralized with the hypermetropia (presbyopia) of middle and later life. But a patent hypermetropia has a tendency to increase with the onset of presbyopia.

Experiments (Wunderman) on the economic values of vision in the various trades and occupations have shown very naturally that coarse workers and laborers get along on very much less vision than skilled or professional workers. But here again it must be remembered that scientific and practical visual acuity are not one and the same thing, and that the deductions of these experimentors, with their findings, are rather of less practical than theoretical value. An individual may be found scientifically deficient, and yet be practically efficient.

In whatever walk of life, damaged vision means less ability to retain, but especially to obtain employment. The loss from defective or damaged vision is less as age advances for the reason that part of this loss is lost in the usual loss of usefulness from old age. This is, of course, only relative, for both together make the absolute loss of ability larger. The matter of damaged or defective vision for the various occupations and with certain ages can be made determining factors in the admissibility, because of their relative efficiency, of aliens. The efficiency of an alien with a certain degree of visual defect should be determined in conjunction with his occupation and age. Mathematical computation places the earning ability of the visual power as equal to the functional activity times the square root of the competition. While this again is very theoretical, it is a formula that may have a value when the efficiency of a large number of individuals is to be rapidly considered. It is further estimated that unskilled labor can afford to lose one-half of its vision without economic loss, while skilled labor cannot afford to lose more than one-quarter. When a laborer's vision falls to a 1/20 part he is to be regarded as practically blind; and a skilled laborer is practically blind when his vision falls to a 1/7; in other words, the range of vision for the skilled must be at least between .75 and .15, the laborer's between .50 and .05. These estimations are for the eye having the maximum vision, the other eye may have less, but is not considered in these computations. According to other estimators this latter is not entirely correct, for they credit a one-eyed person of the higher ranged skilled type with a loss in earning power of between 20 and 30 per cent.; and for the lower ranged type a loss of between 15 and 25 per cent. On this scale reduction in the vision of the other eye below the eye in question would have a tendency to further reduce the earning capacity.

Among those requiring the higher range of vision are placed the professions of medicine, law, and theology, students of all professions, engineers, fine mechanics of all kinds, transportation operators and employees, telegraphers, etc. In the lower range are all unskilled laborers, glass workers, quarrymen, miners, building workers, farmers, and the like occupations. These classifications are not intended to be exact, but they do form a rough basis for the practical treatment of this subject. All members of the same trade do not demand the same amount of vision. The personal element, individual skill, etc., are modifying factors. Besides, it must be remembered that the test type determination of the amount of vision is not the actual amount of vision, nor does it give a strong clue to what the vision can actually and practically do. Most individuals can reconcile their vision to their work, or, better, they seem naturally to select for themselves the work best suited to their vision.

Myopes especially, seem to select work best suited to their vision, and they are seen to be prolific in such occupations where distant vision is of no account. They seem to be in a class by themselves, and their usefulness cannot be judged by the same standards as other workers. On the other hand, in transportation occupations, aside from the importance of color vision, the question of distance acuity is of paramount importance. The United States Government controls and enforces the visual examination of those engaged in the navigation of vessels. No license is issued or renewed to those who do not pass the color or distance tests. These tests should be carried out with uniform illumination and attention should be given to latest hypermetropia. The government has, however, no control over railroad and other transportation employees. It is true that the railroads are now conducting examinations of their employees and prospective employees, but the examinations lack uniformity. In interstate traffic of all kinds, not alone railroad, the government could exercise control without interfering with State rights, and as for intrastate traffic the various States could easily be made to see the advantage of allowing the Federal government, through its public health service, to assume control. The operators of all vehicular traffic, even of automobiles, operating between the States should be examined to determine their visual acuity.

With railroad operators distant visual acuity has a more practical significance because of the position of signals which is of such vital importance to railroad operation. It has been estimated approximately that the presence of the semaphore blade should be determined at from two to three miles by the average eye, and as it takes about two thousand feet to bring a high-speed six-car train to a stop, it is essential that the signal should be determined at about half a mile. It is wisest to require normal vision of railroad operators without the correcting influence of glasses. Since even if lenses do correct, an accident to the lenses may mean an accident to the train. The factor of latent hypermetropia must be eliminated, for while a young adult may have normal vision with a latent hypermetropia when it becomes patent in later life, vision may be greatly reduced even to 20 200, with the possibility that even glasses may not correct. Most railroads now reject latent hypermetropes. The determination of this condition is simple. If an individual will see as well with a one or two diopter plus lens (convex) he has a latent hypermetropia equal in degree to the power of the lens he accepts. It goes without saying that myopes should not be employed in these occupations, even though a slight myopia tends to disappear at the age when a latent hypermetropia is most likely to manifest itself.

While hypermetropia handicaps in later life, myopia does so, if at all, in early life. At all events the handicaps of myopes are greatly overestimated, except, of course, in the high myopes, usually in those who have a myopia of ten or more diopters. In these, besides the refractive error, there is usually a pathological condition of the retina and choroid. Otherwise than in such conditions myopes have an almost unlimited field of visual usefulness and occupation. Indeed, it is said that civilization tends toward myopia because the fine analyses, dissociations, and synthetizations of civilization must be carried out at a near point. It is the combination of the many near-work specialties which produces the large finished product. It is only the coarse and crude work that can be done at a distance. Fine work means near work, coarse work means distant work. It is the near requirement of the modern specialized occupations which gives rise to the eyestrain and other eye reflexes. It is particularly the individual with a tendency to hypermetropia who feels the brunt of these requirements. The nearsighted individual, except if he is so nearsighted that his focus is actually tangent with his cornea, or even in back of it, so to speak, does not need distant vision—he can walk to it. It is not surprising, therefore, that so many myopes go without correction. Yet correction for even only a fair degree of myopia opens to them a new world, and they cannot understand why they went so long a time without correction. The farsighted individual without correction strains his eyes when doing the ever present near work. The myope seeks his distance, focuses on it, and is comfortable. He does not see his friends pass him, not because they are necessarily out of focus, but because his eyes are busily engaged keeping their own focus, to keep from strain in trying to negotiate various other points. The reputation of dullness of expression that the myope has because his eyes are always out of focus is not, therefore, always true, because as a matter of fact the myope does keep a focal point, be it ever so near.

Yet myopia of a high degree is a great handicap. The savage is not myopic because his survival depends upon his distant vision. On the other hand, it is said that the savage's vision is not better than the civilized individual's but he apparently sees better because he is educated to observe and interpret properly what he sees. This is undoubtedly the case with the high myope, who gets along though he does not see well, because he learns to observe, to interpret, and to accommodate himself to circumstances. The question of accommodation to conditions is illustrated in the high percentage of myopes in such trades as the jewel, lithographic, and printing trades. The theory that these trades cause this defect in their workers is not as plausible as the theory that myopes from natural adaptation choose these occupations, which they may be able to do better because they are myopic. This should be considered in judging the efficiency of individuals having this defect of vision to a greater degree but who are engaged in these occupations. In Germany, a country in which the sciences are highly developed, myopia is extremely common. It is estimated that about 60 per cent. of the student body and a lesser percentage of the adult population are myopic. The large amount of myopia among the German school population is placed at the door of the unhygienic type which is used in all but scientific publications, and which these otherwise enlightened people refuse to change from a sense of pseudo-patriotism. Myopia is so much on the increase in that country that if it continues to increase in number and degree they may become, so to speak, racially myopia-blind. The relative percentage of myopes increases with age because, in all likelihood, the range of accommodation becomes less as the child grows older. Whatever the cause, however, the increase in the number of myopes makes it imperative that this condition receive more study with the view of instituting methods of prevention and control.

It is to be remembered that the near work or reading distance and distant visions are not in a fixed ratio to each other; so that while a lens may give a standard or nearly standard reading distance vision, the same lens may not nearly give the standard 20 20 vision for distance. There does not seem to be a correlation between the two, either when corrected or when uncorrected. In other words, it can perhaps be said that the correction which should give at least a degree of vision which ought to be minimum for distance becomes in fact only the maximum for near work vision. Confusion is frequently caused by designating the degree of vision by other fractions than the standard Snellen fraction. While 20 20 is standard normal, 20 40 is not properly designated as one-half vision, nor 20 200 as one-tenth vision, because the Snellen standard fractions are only relative working bases for comparison and are not the equivalents of actual fractions, since as there is no standard vision real enough to call the unit, it is obviously impossible to designate an aliquot or other part of that vision.

In children the question of visual acuity has more than a present material or clinical import. The eyes are the main channels through which the mind receives the stimulation necessary to its development. A child with defective vision loses these stimuli, and if by reason of the visual defect enough of these stimuli are deprived from the mind, that mind will be defective. Ofttimes a child rated as mentally defective improves, to become even normal when the eyes are corrected to give even only a fair

degree of vision. Defective vision is often coupled with mental and physical degeneration. In many intelligence and good vision seem to travel together. In others, however, the degeneration which is only apparent is arrested and made to rise when the vision is corrected.

Competent ophthalmological examination can nearly definitely determine the cause and the degree of the refractive error of ophthalmic disease. There is, therefore, little excuse for any one to remain without at least a fair degree of visual acuity. But the degree of error indicated by the instrumental examination does not always coincide with the amount of correction that the patient's eyes will tolerate. The lenses must usually be modified in accordance with the individual tolerance, at times giving a degree of vision far below the standard and far below what is desired. The visual acuity must often be sacrificed to comfort. Very often full correction is not possible. The degree of refractive error with its equivalent correction as ascertained by instrumentation does not solve the problem of refractive errors. As in general medicine, each individual case must be separately considered, and the correcting lenses suited rather to the patient than only to his eyes. The general practitioner is frequently called upon to determine, roughly to be sure, with the test type, degrees of refractive errors. He should be able to do it more accurately and be able to determine the type of refractive error, and in simple cases even to prescribe the appropriate lenses. The optometrist would have a much smaller field. At any rate he should be able to say that a case needs the services of an ophthalmologist.

It was the general rule to give hypermetropes the least amount of correction that gave clear vision; and to insist that myopes get the highest correction in order to arrest the condition. Astigmatism always receives the full correction called for, and which the patient will tolerate. Now, however, in high myopes, full correction is not advised. Many times it causes great discomfort, may be harmful, and a lesser correction is certainly fraught with no danger. The extremely thick lenses called for in high myopia are serious cosmetic objections. It should be considered when treating high myopics. Thick lenses are in a manner disfiguring, and patients hesitate to betray broadcast their severe defect. Many patients, especially women, insist upon thinner glasses even at the sacrifice of better vision. Many mechanical methods are tried to reduce the thickness of the lenses and thus mask the condition. Lenses of higher refractive index would reduce this objectionable feature. Very nearsighted persons are not looked upon with a great deal of favor, not even socially, probably because the term nearsighted is too often used to define an analagous mental complex.

While the public seems to realize the advisability, and even the necessity, of obtaining as much acute vision out of their eyes as possible, it may seem odd that so great a number of persons are satisfied with the optometrist type of visual correction. The great impetus that this business has received in recent times does not, however, mean that there has been a decline in the work of the legitimate ophthalmologist; it indicates merely that the optometrist is an incidental evil in a movement for the good, namely, the movement for the conservation of vision. In large part the optometrist caters only to the crude, to those who in the absence of the optometrist and his advertisements would not recognize the necessity for better vision and lens correction. The optometrists sell glasses to all who may apply without regard to their needs, or whether they will be benefited or harmed by them—that is their business. Not everyone who applies to the ophthalmologist or even to the general practitioner gets lenses, for there are other indications which the optometrist does not recognize. Those for whom better vision means better work apply to the ophthalmologist sooner or later. This class of individuals is an ever-increasing one as more skilled labor and professions are demanded.

Physicians who wish to take up the practice of ophthalmology, in which refraction forms such a large branch, should first be certain that their own vision is good, conforms to the standard, or is capable of correction. In this work one is handicapped whose vision is below standard. With various degrees and kinds of corneal or lens defects it is very difficult and frequently well-nigh impossible to make the necessary computation corrections necessary to be made because of the defect of the examiner. Young men who have not yet even accommodative error do the best work. Many of the older ophthalmologists engage young men as assistants to do especially this branch of their work.

And, finally, it is to be remembered that after the many trying and time-consuming examinations, with the many modern delicate instruments for the determination of the error, both the physician and the patient are dependent on the optician in having the prescription for the lenses filled; and that in many instances the prescriptions are not properly filled to the harm of the patient and the chagrin of the physician. This can in a manner be obviated by sending patients only to opticians who do not attempt to refract their own cases but who devote their entire time and equipment to the lens production, but particularly by testing the lenses obtained with the lens-measure or spherometer, to see whether they conform to the prescription.

In conclusion it is urged that it is important to conserve visual acuity in the race, and that to accomplish this early diagnosis is important; that immediate correction of defects must be instituted; that the general health must be improved, and that hygienic measures as regards school life, occupations and industries, illumination and improvement in the reading type form must be enforced. As with other human ills which it is sought to eradicate in the present generation, but especially in the future, the eugenist will offer his theory as the means of solution. If it will be remembered, however, that real eugenics concerns itself not merely with the nature and reproduction of racial qualities, but more especially with their *nurture*, much good can come from this movement in this instance also. In visual defects the heredity incidence is small and knowledge on the subject almost negligible. Selective breeding for the eradication of racial ills and the production of racial qualities is still a phantom, but prevention by prophylactic measures is a reality.

351 East Fiftieth Street.

The Paths of the Internal Secretions.—R. Lépine points out that a part of the internal secretions passes into the lymphatics and a part passes directly into the blood vessels. In addition certain internal secretions exist in the walls of the blood vessels themselves.—*Revue de Médecine.*

THE PHYSIOLOGY OF WORRY.

By ERLE D. FORREST, M.D.,

BOSTON, MASS.

INSTRUCTOR IN PHYSIOLOGY, TUFTS COLLEGE MEDICAL AND DENTAL SCHOOLS.

With the possible exception of those in the period of happy childhood, everyone is at times a victim of worry. In fact, the average individual thinks of and accepts worry much as he thinks of and accepts disagreeable weather conditions—as one of the bitter things of life which must be taken with the sweet. In other words, he regards it as a fact, but does not attempt to analyze it. The wisest thinkers of all times have recognized the condition, and many well-known writers have expressed their views of its psychology. What has not been sufficiently recognized, however, until very recently, is the importance of worry, not merely in itself, as implying the absence of happiness, but as the cause of ills far greater than itself, the cause predisposing to secondary manifestations which would otherwise have been escaped altogether. Having fully comprehended this fact, the next logical step in scientific progression is to determine the exact mechanism by which these disturbances are brought about. Through the conjoined efforts of psychologists and physiologists, we are just beginning to reach the true physical basis of this important subject.

The keynote of worry is beyond doubt a disturbance of the mind. It may be defined as the restless consciousness of all encumbrances which we accept under protest. To elaborate this definition, it is the mind's unrest about anything which concerns us, whether it relates to our future, our dear ones, a cause we have espoused, our happiness, our salvation, our means of support, our position in life, our health, our fate, or our success in general. It does not consist solely in our interest in all these things; it is rather a disquietude arising from a feeling of helplessness before the various chances and claims of life. The popular opinion seems to be that the mental condition is one of depression, possibly because the physical manifestations are chiefly depressive in nature. The fact cannot be too strongly emphasized, however, that the primary mental condition is one of overactivity, and moreover, overactivity along lines of fixed ideas.

Without taking up individually the phases of worry brought about by the various specific causes, the physical manifestations of worry in general may be said to be—depression of respiration, sighing, disturbances in rate and force of heart beat, vasomotor changes, disturbances in secretion, pallor, cold extremities, relaxation and decreased motility of the alimentary tract, dilatation of the pupil, loss of weight, insomnia and general physical exhaustion. These disturbances may vary in their prominence, and may appear as groups of symptoms characterizing well-known diseases. Thus, worry is sometimes an important agent in the production of diabetes, gout, exophthalmic goiter, and chronic heart disease.

Inasmuch as worry is primarily a disease of the mind, and since every portion of the body is intimately connected with every other part by a network of nervous tissue of great complexity, we naturally seek for the causes of these manifestations, first of all, in the nervous system.

In every individual, at a given time, there is a limited amount of potential energy stored up in the cells of the brain. This function seems to rest in the chromatin granules of the nerve cells, and it has been shown repeatedly that a liberation of nervous energy, whether in response to a psychic or sensory stimulus, results in a physiological degeneration of the chromatin granules, and consequently of the cells themselves. Obviously, a prolonged discharge of nervous energy diminishes by so much the amount left in the brain cells. Furthermore, stimuli of sufficient number, intensity, or duration may cause exhaustion and death.

Exactly this phenomenon occurs in the state of worry, except that the degree of fatigue rarely reaches the fatal extreme. Through mental overactivity, and the corresponding chromatolysis in cells concerned in mental processes, discharges of nervous energy to all parts of the body take place through the cerebrospinal axis and the sympathetic system. Whether the action of a given structure is augmented or inhibited, of course, depends upon its inervation. One of the most constant effects of such long-continued discharges, however, is the production of a certain amount of tonic contraction of most of the voluntary muscles, which, if at all noticeable to the individual, he describes as a slight increase of body tension.

A physiological degeneration of nerve cells is normally offset by a slow regeneration, occurring during the periods of physical and mental repose. In worry, because of the fact that the catabolic process is at first more rapid than the anabolic, gradually diminishing as the lower limit is approached, and because continued mental activity gives rise to insomnia, a period soon arrives when the expenditure of vital force in the shape of obvious work done has reached a point where the regenerative process, slow as it is, is just about able to offset the breaking down. The phenomena expressing the depletion of the vital force are termed "physical exhaustion." This is to be distinguished from "shock," wherein the stimuli lead to no obvious work done, and the expenditure of energy is extremely rapid.

The sympathetic system, probably because of its intimate relation to vegetative functions, seems to be susceptible to a much slighter degree of stimulation than are the nerves of the cerebrospinal axis. When, in the course of events, therefore, the latter nerves are no longer able to respond adequately to the stimuli arising from the mental activity, the sympathetic is apparently capable of carrying on functions even greater than those which it is normally called upon to serve.

Bearing these facts in mind, we see a possible explanation of some of the various physical phenomena. For instance, stimulation of the sympathetic, with a decreased activity of the motor oculi nerve, causes dilatation of the pupil. Depression of the vagus, phrenic, and intercostal nerves decreases the breath rate. The sigh, so often observed in worried individuals, is simply a very deep inspiration which occasionally takes place to compensate for what would otherwise be insufficient oxygenation of the blood. Through depression of the vagus and the simultaneous stimulation of the sympathetic, the heart action frequently becomes rapid and weak. The vasomotor changes are chiefly constriction of the peripheral vessels, due to stimulation of the sympathetic nerves. In this connection the reciprocal action of the veins of the omentum is brought into play, these vessels often

becoming enormously distended with blood. Constriction of peripheral vessels, combined with enfeeblement of the circulation, accounts for the pallor and cold extremities so often seen. The secretions are often decreased in amount, through narrowing of the vessels supplying the glandular tissues. The extremely dry mouth and lips which probably everyone has observed when he has been worried, is a familiar example of this. The stimulation of the sympathetic may, on the other hand, be so severe as to bring about increased secretion in spite of the diminished blood supply, as is evidenced by the so-called "cold sweat." Inhibition of motility of the stomach and intestines appears to be brought about by stimulation of the splanchnic nerves, again a part of the sympathetic system.

In addition to the nervous system as a means of coordinating the various parts of the body there is a method which makes use of chemical processes. In some of the lower organisms this latter method is the only means of unification and is developed to a relatively high degree. The difference between the two methods is essentially one of time, the nervous system being obviously the more rapid by far. These chemical substances have been given the names "hormones" and "colyones," according to whether their functions are those of augmentation or inhibition. They are all included under the general heading of "internal secretions."

Internal secretions are substances produced by gland cells from raw materials furnished by the blood, which are afterward passed back to the blood or lymph stream, to assist in regulating the general nutrition of the economy, or to serve some more specific purpose of equal importance to the organism. They differ from the better known, or external secretions in that in all typical cases the latter are poured out upon epithelial surfaces which communicate with the exterior, while the internal secretions are discharged upon the closed endothelial surfaces of the blood and lymph vessels. With their development in any organism, a susceptibility to their action must arise in certain of its structures. In the broadest sense, internal secretions must be looked upon as something common to all active tissues, but the best known and probably the most important ones are produced in the liver, pancreas, thyroid, adrenals, pituitary body, and probably the ovary, testis, thymus, kidney, and spleen. From the standpoint of their importance in worry, those derived from the pancreas, pituitary body, thyroid, and adrenal glands seem to occupy first place according to the theories evolved as the result of the most recent investigations.

For experimental corroboration of our theories we are compelled to make use of animals, such as the dog and cat, because of the fact that chemicophysiological experiments such as these necessitate extensive and dangerous surgical procedures. Therein lies a great difficulty. Although the animals are readily obtainable we are never sure that a condition of worry analogous to that found in the human organism is simulated. These animals are, however, visibly susceptible to agencies producing fear, and by modifying the results obtained while they are in this state, in accordance with the intimate relation known to exist between fear and worry, many of the theories regarding the influence of the internal secretions may be substantiated.

The function of the internal secretion of the pancreas seems to be that of assisting in the combustion of glycogen, the product of starchy materials ingested as food, in the muscles. Muscular energy is derived from this oxidation, but in order for it to take place two ferments, one produced in the muscle itself, and the other the internal secretion of the pancreas, must be present in quantities of a certain definite proportion. If the balance is destroyed it cannot take place, and the sugar accumulating in the blood to more than the normal percentage, appears in the urine.

Two theories as to the part which worry plays in diabetes deserve consideration. The first is to the effect that the pancreatic ferment is decreased, owing to constriction of the blood-vessels in the glandular tissues. The other is that by stimulation of the sympathetic nerves the secretion is increased. The latter theory seems to have the more supporters, but in either case diabetes results from an overturning of the balance between the muscle ferment and the product of the islands of Langerhans.

Worry also seems to increase the internal secretion of the pituitary body. Recent experiments show conclusively that an excess of pituitrin in the blood, without other complications, produces a marked rise of blood pressure and a slowing and strengthening of the heart beat. It appears to slow the heart by acting upon the peripheral endings of the vagus, the nerve whose function it is to bring about that phenomenon normally. An interesting feature of its effect upon vasomotion is that while most of the peripheral vessels are constricted the arterioles of the kidneys are dilated, allowing an abundant supply of blood to those organs. At the same time, pituitrin exerts a direct stimulating effect upon the secreting cells of the uriniferous tubules. These three factors—increased blood supply of the kidneys, increased blood pressure, and hyperactivity of the secreting cells—may well account for the marked diuresis so often observed in worried individuals.

Occasionally after long-continued worry or extreme fright, the symptom complex—known as exophthalmic goiter—is observed. It probably does not affect an individual unless a previously enlarged or disturbed thyroid gland is present. However this may be, the disease is undoubtedly associated with a hypersecretion by this gland. Since it is supplied by the sympathetic it seems reasonable to infer that this oversecretion is brought about by the stimulation of its controlling nerves. An excess of this substance in the blood, in contrast to the effects of pituitrin, dilates peripheral arterioles, probably by a direct action on the muscle in the vessel walls, bringing about a visible flushing of the skin. It also appears to have an antagonistic effect upon the substances which influence the nutrition of the body, as is evidenced by the rapid loss in weight in this disease and the excretion of large quantities of nitrogen, carbon dioxide, and water in the urine. That it has a definite action upon the nervous system is shown by the tremor usually present. The pulse is at the same time rapid and throbbing in character.

The effects of the internal secretions thus far considered must not be regarded as constant manifestations of this emotion. In fact, the cases are relatively rare in which diabetes and exophthalmic goiter do occur. Inasmuch as we have come to ascribe to all body tissues powers of secretion, is it not entirely reasonable to presume that secretory disturbances in one organ may be offset or held in check in a majority of cases by products of other structures? We know this to be an almost universal principle in ani-

mal function, exemplified by the opposed actions of the vagus and sympathetic in the control of the heart. Denied this liberty, we can only, at present, make use of the vague term "individual susceptibility" in explaining this seeming inconsistency.

There is an internal secretion, however, that of the adrenal glands, which appears to be always associated with the most constant effects of worry. Adrenalin, or epinephrin, as it is called, is an excellent example of the manner in which most of the internal secretions and the nervous system interact and supplement each other, for it has been shown that it does not act upon any organ or tissue which has no sympathetic or autonomic nerve supply. In fact, its point of attack appears to be the end arborization of the nerve fiber where it joins the muscle or tissue. The presence of physiological quantities of adrenalin in the body, seems to be a necessary condition for the normal functioning of the entire autonomic system.

The secretion of adrenalin is controlled by the sympathetic and is increased in worry. We cannot say that its presence in the blood in abnormal quantities is responsible altogether for the phenomena which are dependent upon the autonomic nerves, for we have seen how the increased stimulation of the sympathetic, by means of mental overactivity, can bring about these things. It does, however, magnify the action of the sympathetic and is capable of maintaining this action alone, for a considerable period of time after the sympathetic stimulation has been removed. The latter phenomenon is accounted for by the fact that there is an autogenous continuance of most of the internal secretions, including adrenalin. In other words, these substances, coming in contact with the tissues which originally produced them, tends to stimulate still further production. After a time, however, even this mode of adrenalin derivation ceases, for the blood gradually gives up its epinephrin by aeration in the lungs.

After the foregoing discussion it can readily be seen that many features of worry have not been considered. This condition together with its allied emotions, constitutes an enormous field for further scientific investigation. In view of the rapid improvement which modern laboratory technique is undergoing, and the increased interest with which experimentalists are viewing psycho-physiological matters, there is a great probability that within the next few years many of the remaining doubtful points will be satisfactorily explained.

THE MEDICAL ASPECT OF ATHLETICS.*

By ROBERT E. COUGHLIN, M.D.,

BROOKLYN, N. Y.

In this age of athleticism we are very apt to lose sight of the fact that athletics may be for evil as well as for good. No one will deny the good accomplished by the introduction of athletics into our public and private schools, colleges, associations, clubs, societies, leagues, boy scout organizations, army and navy, turning clubs, and other organizations where men and boys gather together for recreation, study, and pleasure. One has only to observe the steady growth and improvement in the physique of the growing boy who takes part in athletics. In Japan, Norway, Sweden, and Denmark as well as in Germany the physical training incident to the activities carried on in their turning and wresting clubs undoubtedly improves the physical make-up of their male population. America is distinguished by the advance which goes steadily on in the physical training of the school children. This physical training is a salient feature of our American school education. Our ancestors with fewer gymnasiums were a remarkably sane people, however, and we may ask ourselves the question if the great increase in insanity has anything to do with our present system of physical training. Asylums and hospitals are crowded and athleticism increases in proportion. One rarely sees the statement that the worthiest college student is the best athlete, as in the case of Albert Cyril Rothwell of the class of 1914 of Columbia.

It would be interesting to know if physical training will accomplish a decrease in street accidents, an increase in moral tone, an improvement in physical condition, a decrease in gangs, a decrease in truancy and better discipline in our boys. There is reason to believe that physical training means competitive games in which the vital organs are overtaxed. When this obtains a great injury may be done to a boy's constitution. The injury may be a permanent one and markedly shorten his life.

It has been proved beyond question that immoderate college athletics lead to physiological hypertrophy of the heart. Athletic training leads at first to physiological hypertrophy, but when prolonged and marked by severer athletic contests it usually leads to hypertrophy plus dilatation of a variable degree frequently marked by valvular insufficiency. Functionally the hypertrophied heart, even when dilated and giving distinct evidence of valvular insufficiency, may prove more fitted to carry the man through a severe athletic contest than a normal heart would be. On the other hand, acute cardiac dilatation occurs more frequently in athletes and men used to severe muscular strain than in the normal man and the effects are more prolonged and severe. L. Shumacker and W. S. Middleton conclude that there is reason to believe that for normal human activities an athletic heart is distinctly disadvantageous.

The death of Clarence Panzer of the National Guard brought to light the fact that shortly after his enlistment in 1911 he developed an athletic heart with a certain amount of hypertrophy and dilatation. Later on a valvular lesion occurred which aggravated the cardiac trouble. He appeared to be a man in robust health and of strikingly good physique. Three months before his death he was given three inoculations of typhoid vaccine. An attack of the grip, mild in character, apparently was sufficient to cause his death. The influenza germs had found a place of lowered resistance. An attempt was made to prove that the typhoid serum was the cause of death, but this was not proved by the facts in the case. The autopsy showed death to have been caused by a severe type of endocarditis with general septicemia. Clarence Panzer's brother, George, in spite of his magnificent physique, developed tuberculosis and later heart disease, finally dying after four years' illness.

Carefully collected statistics show that deaths of athletes are caused by the following diseases in the order of their frequency: cardiac diseases, tuberculosis, typhoid fever, pneumonia, and Bright's disease. The dangerous games indulged in with fatalities in the order of the greatest danger are football, baseball, and boxing. In looking over the history of boxing we find that many champions

*Read before the American Medicopharmaceutical League, May 25, 1914.

have died from tuberculosis. Whether this disease may have been produced by excessive athletic training in preparation for the contests, severe punishment, and tests of endurance in the ring, or lax habits of living when out of training, it is difficult to state. The writer once heard a second speak very disparagingly regarding the championship possibilities of a very promising young pugilist in the following words: "He'll never be a champion because he stays out late nights and smokes cigarettes in training." And although this young man's prediction was made fully two years ago this particular pugilist has never become a champion, though he has knocked at the door several times.

Undoubtedly athletic training does promote the moral tone for all athletes, and trainers know the importance of correct living along moral lines which is so necessary to produce good results. Early to bed, early to rise, no smoking, no drinking, no sexual indulgence, have been a part of the rules of every training camp since the beginning of time. Old time observers would refuse to have confidence in a fighter who had recently married. They used to say it would take about a year for him to round into form again. Knowledge of the internal secretions teaches us that there was a basis for the latter belief for we all know how easily the individual becomes obese and mentally and physically sluggish, with excessive venery. To stimulate the vital forces a sufficient amount of testicular secretion should be stored up and without this the male may become slow and lazy. Without this natural secretion or stimulant he will not enjoy active exercise and will not profit by it when he takes it. Asexual obesity is a well established and well recognized ailment and calls for hygienic measures in the treatment of this condition.

The following case report shows the evil which may be occasioned by immoderate athletics. It is an exceptional instance but it may serve to help in a consideration of the subject of athletics when carried to excess.

Case.—G. L., age 20; occupation, clerk; nativity, United States; physique not robust, of the blonde type, not large in build. Family history negative, except that a sister died at the age of thirty of heart disease after nine years' illness. Previous history shows that patient never had rheumatism, tonsillitis, scarlet fever, or any other infectious disease or condition. History of development: when the patient was fourteen the family physician first noticed on examination a degree of cardiac hypertrophy with a slight aortic regurgitation, which he believed was due to athletic training, gymnastic exercises, and outdoor sports. The boy was advised to discontinue all athletic work and at the age of seventeen his father sent him to Switzerland, where he attended school for a period of two years. While in Europe he disobeyed all instructions and entered games even to a greater extent than he did in America. In one contest he chinned himself fifty times. He returned to America, however, in apparently good health. A short time after arriving home he began to have attacks of indigestion marked by vomiting, at times with severe headache. Urine was not examined. March 13, 1913, he was referred to an ophthalmologist because he appeared to have a cold in the right eye. At this time he had a cold in his head with a slight sore throat. There was a severe headache also. Right eye was marked by redness. Examination of eyes showed: vision in right eye 1 15, vision in left eye 1 12; double sided chocked disc with some hemorrhages; numbness of right arm and leg; some loss of power on right side; brain tumor suspected; urinary analysis showed a large amount of albumin, 16 per cent., a large number of granular casts, an acid reaction, and a specific gravity of 1006. Examination of the heart showed an accentuated second sound with a loud murmur heard over the entire cardiac region. Blood pressure 250; heart intensely hypertrophied. Murmur could be heard in vessels of neck and lower extremities. Apex beat displaced downward as far as the waistline. Liver much enlarged; no ascites; arteries hard and tortuous. Examination April 30, 1913.—Eye findings: Vision 1 12 and 1 18; extensive hemorrhages in fundus; signs of edema of limbs; some dyspnea. Diagnosis: neuroretinitis alburinuria; chronic interstitial nephritis; cardiac hypertrophy; aortic regurgitation; epistaxis; organic loss of sight; uremic coma; date of death, August 14, 1913; age at death, 20 years and three months. In the words of the family physician: "In my judgment the organic trouble was brought on by athleticism only."

General Considerations.—The foregoing case report would suggest the fact that this young man should never have been allowed to take part in athletic competitive games. There was some unusual sensitiveness to muscular excess. His muscular system was undervalued and there was not adequate development. The cardiac murmur was recognized when he was fourteen years of age and his family physician is positive that athletics brought on the damaged heart condition. He had never had any of the infectious diseases or infective conditions such as scarlet fever, rheumatism, or tonsillitis, which are known to produce cardiac complications or sequelæ. It is evident that there was no watchful care such as we should expect on the part of those who manage athletic games and sports. The boy's best interests as regards his health and future existence were not conserved by his teachers and those who were over him. His trip to Switzerland was disastrous because there was no vigilance displayed. The boy's inclinations and bent were along the athletic competitive line, probably because he excelled. There was no repression because his condition was not watched as it should have been by medical men well qualified to judge of a proper amount of exercise compatible with a damaged heart. The boy went almost blind before it was realized how serious his malady was. The damage to his circulatory system must have been enormous, for with the decompensation of the heart there were all the sclerotic tissue changes in the arteries, the kidneys, and the liver. It is interesting to note the high systolic blood pressure in a youth twenty years of age. Unusual sensitiveness to muscular excesses during the period of boyhood must be considered in relation to immoderate athletics in the growing youth. Age is a factor of great significance. It is doubtful if a person's constitution *per se* is made better or is improved by athletics. It must, however, be taken into consideration when one is to determine the fitness of a person to compete. Good nutrition, a competent nervous system, and adequate development must not be undervalued. Personal superiority and the stimulus of victory may make for the overdoing of deeds with their consequent ill effects.

Conclusions.—(1) Physical training is a very important factor in our American school system of education. (2) An athletic heart is distinctly disadvantageous for normal human activities. (3) An athletic heart may be better fitted to carry a person through an athletic contest than a normal heart would be. (4) Athletes appear to be as susceptible to infectious diseases as other persons in the ordinary walks of life. (5) Deaths of athletes are caused by the following diseases in the order of their frequency: cardiac diseases, tuberculosis, typhoid fever, pneumonia, and Bright's disease. (6) Fatalities occur most frequently in the games of football, baseball, and boxing in the order of the greatest number of deaths per year. (7) Athletics increase moral tone and discipline. (8) If possi-

ble competitive features in athletics as practised in our public schools should be eliminated. Feats of strength and endurance should also be eliminated. (9) All means should be used to diagnosticate diseased conditions in schoolboys and special attention should be paid to the circulatory system, especially the heart. Tests should also be made for vasomotor tone and finally the nervous system and the condition of the kidneys should not be undervalued.

428 Forty-seventh Street.

ACUTE SUPPURATIVE OTITIS MEDIA.

By H. LELAND FIFIELD, M.D.,

SYRACUSE, N. Y.

EYE AND EAR SURGEON TO THE SYRACUSE HOMEOPATHIC HOSPITAL.

In the consideration of acute suppuration of the middle ear it will be my aim to call attention to the common form or the condition we most often meet, and the more latent and at the same time the more dangerous. There is no class of cases with their attendant complications which gives the physician more anxiety than suppuration of the middle ear. The time has long since passed when we hear of a physician advising the parents of a child who may have a discharging ear to delay treatment until the child has reached puberty.

There are two well-defined infections of the middle ear which are distinctly different as regards both the symptoms and the end results. I think I am safe in saying that a goodly number of intracranial complications have been caused by the latent form of otitis which has escaped diagnosis until treatment was useless. There is no condition that we fear more than an extension of an inflammation to the adjacent tissues from the tympanic cavity or mastoid.

In otitis there are two well defined cocci, a non-capsulated bacterium, the one most often found, and the *Streptococcus mucosus* the capsulated bacterium. The former occurs as a chain of small cocci while the latter is seen arranged in a chain usually of four together, each individual coccus having a well defined capsule.

Otitis Media from the Non-capsulated Coccus.—This condition which is the most frequent and most easily diagnosed is in the large majority of cases a secondary infection coming on after the exanthemata (measles, scarlet fever, diphtheria, whooping cough) tuberculosis, syphilis, tonsillitis, growths in the pharynx (adenoids), extension from rhinitis or empyema of the nasal accessory sinuses. One cause is the influx of water through the Eustachian tube into the middle ear, in which nasal douching and diving play their part.

Otitis media is easily recalled by its symptoms—a dull full feeling of the ear for a few hours then a sharp stitching piercing throbbing pain coming on suddenly; a rise of temperature to 102°-104° with or without a chill. If a child who may be suffering from any of the diseases mentioned has a chill look for a middle-ear involvement; a diarrhea which may appear at the same time tends to lead us away from the ear.

If we examine the ear we find it sensitive. The external canal may or may not be swollen, the drum is swollen, there is a diffuse congestion over the whole membrane, the details are gone and the cone of light is missing. There may be a bulging of Schrapnell's membrane and the cuticle of the drum is macerated and heaped up, with later a sticky exudate in the canal.

At this time it is well to do a paracentesis, for if we leave the case to nature she will break down the membrane, finding an exit for the secretions. The pain, if not relieved at once, will be less severe and in a few hours usually subsides. As the pain is due to the pressure in the tympanic cavity it is good surgery to open the membrane early, provided we have bulging. It is, however, impossible at times to prevent further involvement of the mastoid even with an early paracentesis.

For convenience we will divide otitis into four stages, which cover a period of six weeks provided we have no complication:

First stage, serous, 4 to 7 days; second stage, purulent, 7 to 10 days; third stage, mucous, two weeks; fourth stage, catarrhal, two weeks.

In the first stage we have the inception with the pain, increase in temperature, and a rapid progress of the condition with the rupture of the tympanic membrane provided we have failed to secure drainage for the pus during this stage. In this stage we have the inflammation at its maximum, the streptococcus being an infectious agent which works rapidly, reaching its fastigium in four to seven days and then beginning to subside.

In the second stage for two weeks we have a steady flow of pus changing into a stringy, ropy mucoid discharge in the third stage.

In the last stage there is a catarrhal discharge with a cure at the end of six weeks. With the lessening of the discharge we again recognize the anatomical landmarks. One thing we must keep in mind: free drainage is absolutely necessary, and should the wound made in the drum close it will need to be opened again and kept open.

Otitis Caused by the Streptococcus Mucosus.—With this condition we have no severe symptoms. There may or may not be fever. The condition starts as a mild or low grade infection of the tympanum. The patient first notices a slight irritation from noises, and at the same time complains of a feeling of fullness of the affected ear with slight pain. He complains most of the fact that whatever he does he is constantly aware of a dull pain in the ear (organ feeling). After three or four days the pain ceases, no more noises; a little uneasiness on that side at times, but the patient returns to his occupation; he is apparently well for three months or a year, perhaps longer, then without any warning he develops a complication. He has a brain abscess, meningitis, or sinus thrombosis with severe fever; the prostration increases coincidentally with the rapid onset, and now something must be done and done in a hurry.

The *Streptococcus mucosus* enters the tympanum by way of the Eustachian tube and in the tympanum may set up a mild inflammatory lesion. This coccus having a perdilection for bony tissue proceeds to settle down in the bone around the tympanum and goes to work; when the time comes that this inflammation has broken down the wall which separates the tympanum from the surrounding internal structures the patient exhibits symptoms of a complication. It is very seldom that we have the labyrinth involved, but one form of circumscribed labyrinthitis may result from this variety of infection.

When we are called to a case presenting the symptoms I have enumerated we should do first a paracentesis and examine the smears from the secretion of the ear for *Streptococcus mucosus*. If we

are unable to find the coccus then a lumbar puncture should be done, for often when the pus from the ear does not show the coccus the cerebrospinal fluid will present the offender.

Now after we have made smears it is a good plan to proceed as follows: (1) Stain one of the smears with methylene blue to find the streptococcus. (2) Stain another smear with carbol fuchsin to find the tubercle bacillus. (3) Stain the third with thionin to find the *Streptococcus mucosus* (capsular). If we use a concentrated fresh watery solution of thionin we are able to find the *Streptococcus mucosus* arranged in chains of four with a well-defined capsule.

Some time ago I saw a typical case of mucosus infection. A man came into the clinic complaining of a dull heavy indefinite feeling in his left ear, slight pain, no elevation of temperature, pulse normal; in fact he seemed to have very little wrong. He said that in the daytime while at work he was hardly conscious of his ear. On examination, the tympanum showed redness over the whole drum, there was no bulging of the drum, the tests for hearing were poor, all other tests were negative. Otitis media catarrhalis was our diagnosis, and he was ordered to report at the clinic twice weekly for inspection. After two weeks all symptoms subsided except a slight indefinite feeling in the left ear, and he came in a few weeks after to tell us this had gone. He said that he felt entirely well. He was discharged and told to come back in case he had further trouble. Nothing was heard of him for six months until one day he came in with an elevated temperature and a marked nystagmus to the left side. The patient was put to bed and prepared for a mastoid operation. On opening the mastoid the antrum was found filled with a mass of broken-down carious material, the walls of the frontal semicircular canal were carious. A complete radical operation was done and the patient returned to bed. In this case a smear was taken when the mastoid was opened and the *Streptococcus mucosus* was found. For that reason the wound was treated by the open method instead of being closed as in a non-capsular streptococcus case. Recovery was uneventful.

Treatment of Suppuration of the Middle Ear.—In the first form the first step necessary is to secure free drainage, which is best obtained by a paracentesis. In doing this we should exercise in minute detail the strictest asepsis. I irrigate the ear with saline and follow with 1 to 3,000 bichloride. When the ear is prepared a liberal incision is made in the drum. In case there is an opening in the drum it many times is of the small central variety; this should be enlarged, then Siegel's otoscope may be used to draw out the pus.

The practice of inflating the middle ear is dangerous and should be done with extreme care if at all. The application of cold to the mastoid is safe provided the patient has pain and it is not kept on too long a time. Depletion with leeches or the artificial leech may relieve, but one must remember that it may be necessary to open the mastoid at any moment. These cases should be cared for preferably in a hospital where materials are at hand for immediate operation.

In the *Streptococcus mucosus* variety treatment may be stated in one word, operation, and that early. It is, however, the most difficult task to convince such a patient that operation is the only cure, if all he suffers from is the indefinite pain which I have mentioned. The consideration of these two forms of otitis can but show us one thing, and that is, in every case of middle-ear suppuration, where there is pain with bulging we should perform a paracentesis and make smears; if we are unable to stain them we should send them to some one who can, and then we are certain whether we have the *Streptococcus mucosus* present.

The medical treatment in these cases is only rarely of value; the use of the autogenous vaccines has proved beneficial but it does not prevent extension to the mastoid, nor does it cure in all cases; stock vaccines have proved a disappointment to me.

614 South Warren Street.

A RHINOLOGICAL ASPECT OF SOME MENTAL DISTURBANCES.

By J. A. HAGEMANN, M.D.,

PITTSBURGH, PA.

Horace, in the course of one of his poetical epistolæ, says: "If anything affects your eye, you hasten to have it removed; if anything affects your mind, you postpone the cure for a year." One might paraphrase his statement without subjecting truth to a tensile test by saying that parents will provide prompt treatment of possibly minor physical defects in their children, but procrastinate when dealing with a manifest psychic inferiority.

To one who in our era of amazing progress in the realms of physiology and pathology harks back to the elementary days of these sciences, it must be apparent that the early investigators were not lacking in acumen when noting the relationship existing between cause and effect. Expressions which have become idiomatic and enduring took their inception from the nomenclature of these primitive savants. And while some of their theories have in the light of later knowledge proven fallible, the fact nevertheless remains that those who advanced the postulates were remarkably alert.

The spleen was supposed to be the seat of several emotions, such as anger, bad temper, grudge. Hence the expression "to vent one's spleen." When we bethink ourselves that the sufferers from malaria are wont to have a considerably enlarged spleen, and that their disposition is usually not remarkable for amiability, we can readily conjecture that the "grouch" manifested by the patient might have been attributed to the condition of the aforesaid gland. The word melancholy means having black bile. The term itself implies the prevalence of the idea that a certain condition of the biliary secretion bore an etiological relationship to the mental depression suffered by certain persons. If we consider that the roisterers of former days probably awoke with a bad taste and in a penitent frame of mind, we can believe that they fancied their livers required some restorative treatment. Physicians of that day, encountering a case of mental depression of apparently similar type, would probably feel justified in attributing the ailment to the baneful effect of the black bile, and inferentially term it melancholia.

While these and allied impressions no longer prevail, they nevertheless were the antecedents of the modern conception of the influence exerted by noxious substances which are borne along in the blood current of many persons, and the effect they exert upon particular nerve or brain centers. When a toxin like that of diphtheria makes its invasion the system promptly begins to produce an antitoxin. Unfortunately the process is slow and horse-serum containing antitoxin must be administered to supplement that being generated by the respective human economy. If the patient could survive long enough he would probably provide autogenous antitoxin in sufficient quantity to conquer the disease. Contrarily and unhappily the same is, however, not true of some other toxins or substances whose es-

sence we are not yet familiar with. What we do know is that they exert a maleficent influence upon the association-centers in the brain, and that the human economy apparently does not produce any antitoxins to contest the field with the invading host. There can be no doubt that the mental conditions evidenced in children who are suffering from pathological conditions of the thyroid gland are due either to a toxic secretion of that organ or to the lack of an essential element which the gland fails to supply. The vacillating moods which one notes during the establishment of puberty and while the menopause is in progress can probably be attributed to the derangement of the intellectual centers by the epochal secretions of the genital organs at those periods. These disorders come under the observation of every practitioner and are only cited to distinguish them from less evident etiological relationships between certain nasal pathologies and definite mental conditions.

Aprosexia, characterized by inability to concentrate the attention upon a definite object, weak memory, nocturnal enuresis, and tardiness in comprehending abstract subjects is symptomatic of nasal obstruction caused by adenoids or other impediments to nasal respiration. Evidence of this relationship lies in the fact that where the obtrusion is removed the aprosexia soon vanishes in gratifying manner. There has been much contention as to whether the mental sluggishness is caused by the mechanical obstruction to the flowing of lymph from the brain toward the nasal chambers with consequent retardment of the products of metabolism, or whether it is but one of the concomitant symptoms of the general neurasthenia accompanying adenoids. However that may be, we have the empirical knowledge that surgical intervention signifies a promptly resultant progressive mental advancement. A transient mental alienation is sometimes encountered during the course of an empyema of a maxillary sinus. Usually the relationship is sufficiently evident, so that the establishing of a diagnosis is not attended with serious obstacles.

On the other hand, a frequently unrecognized cause of mental depression, and sometimes suicide, is empyema of the ethmoidal cells. The absence of nasal outpouring may mislead one into making a negative diagnosis, although the patient is constantly or intermittently swallowing pus-bearing discharges which perhaps unnoted trickle down the posterior pharyngeal wall. The consequent autointoxication from the biochemical products liberated in the intestinal tract establishes a neurasthenic condition characterized by great despondency. Whether a direct action upon the cerebral association-centers may be exerted by an ethmoidal sinusitis is problematical. The lymph-currents all tend in the opposite direction. Yet one might picture to oneself the possibility of noxious fluids finding their way into the brain via the sheaths of afferent nerves. The mooted point need not evoke controversy, as the solution in either eventuality would be the same—surgical intervention.

Many parents unfortunately suffer from mental astigmatism when it comes to the observation of mental defects in their adolescent children, and despondency in an adult is frequently attributed to some tangible crisis in the patient's temporal or spiritual affairs.

The above-mentioned psychic manifestations of physical abnormalities are not cited with a view of encroaching upon the domain of the alienist and neurologist, but rather to accentuate the necessity for collaboration where obscure mental cases are under consideration. Not all patients with melancholia have nasal disease, neither do all patients with suppurating noses contemplate suicide, but we know that numerous factors enter into the genesis of mental depression in its protean forms. To quote the bard of Avon:

"O, melancholy!
Who ever could sound thy bottom? find
The ooze, to show what coast thy sluggish craft
Might easiliest harbor in?"

HIGHLAND BUILDING.

Medicolegal Notes.

Father's Liability for Medical Services to Son.—Action was brought against a father for medical services rendered to a minor son while the latter was away from home, at school, against his father's wishes. The father did not know of his son's illness, nor that the plaintiff was attending him; the disease was of a private nature, which he would naturally desire to conceal from his parents. His father at the time was contributing nothing to his support. Information of the son's illness could speedily have been conveyed to the father, who resided only a few miles away. The father was held not liable. The court said that there was some evidence of the real need for medical services, none of a failure of duty on the part of the father. Nor was there any exigency, such as the imminent peril of the son and his distance from home, to take the case out of the rule that parental duty must be neglected before a stranger may supply what the parent ought to supply, at the expense of the parent.—Sassaman v. Wells, Michigan Supreme Court, 144 N. W. 478.

Malpractice—Evidence.—In an action to recover damages for alleged malpractice in the treatment of an eye, it is incumbent on the plaintiff to prove that the treatment administered by the defendant was negligent or unskillful, and also that the injuries claimed were the result of such treatment. Proof that a good result was not obtained is, of itself, no proof or evidence of negligence or want of skill. There must be affirmative proof or evidence of such negligence or want of skill, and that the injuries complained of resulted therefrom; and such proof can be established only by the testimony of experts skilled in the medical profession. The evidence in the present case showed that the defendant, after treating the eye a few times, advised the plaintiff to go to an eye infirmary, where it was necessary to remove the eye on account of gonorrheal infection, and there was no evidence to show negligence on the part of the defendant.—Phebus v. Mather, 181 Ill. App. 274.

Right to License Without Examination.—In mandamus against the board of medical examiners of the State of Oklahoma to compel it to issue a license to the plaintiff to practise medicine, it appeared that, on September 12, 1907, the territorial Supreme Court had affirmed the decision of the district court, in a suit brought by the territory, canceling and annulling the territorial license under which the physician had been practising on the grounds of fraud and deceit in procuring the same, and no other license had been issued to him. It was then held that the applicant knew, at the time he made his application, that he was not a graduate of a reputable medical college. It was held that the plaintiff was not entitled to registration.—Board of Medical Examiners v. Gulley, Oklahoma Supreme Court, 136 Pac. 1083.

Board of Chiropractic Examiners—How Chosen.—Chapter 291 of the Kansas Laws of 1913 provides that the state board of chiropractic examiners shall be composed of one ordained minister, one school teacher, and three practising chiropractors of integrity and ability, who have practised within the State for two years. It is held that the act does not require the Governor to appoint upon that board persons who have not complied with the statutes regulating the practice of medicine and surgery. By the power vested in the Governor to fill vacancies, he is authorized to appoint the two other members of the board provided for in the statute whenever three properly qualified chiropractic members are appointed.—Green v. Hodges, Kansas Supreme Court, 138 Pac. 605.

MEDICAL RECORD.

MISCONCEPTIONS REGARDING DEFICIENCY DISEASES.

WHENEVER a new theory regarding the production of any disease is suggested it always, and naturally, is combated. If it is false it will soon be disproved and cast into the limbo of medical fancies, but even if it is basically true it may be overthrown for the time because some link in the chain of reasoning is not properly forged. If it is true and supported by incontestable facts, it may nevertheless be attacked by many honest investigators who have grasped only the broad aspect of the theory and have failed to acquaint themselves with all the details necessary to a full comprehension and appreciation of the new truth. Finlay's yellow fever theory, for example, which blazed the path for the greatest feats of sanitation the world has ever witnessed, made little headway, in spite of his cogent arguments, until the United States Army Commission discovered the fact of an incubation period for the virus in the body of the mosquito. Ignorance of this was the weak link, the strengthening of which made the chain unbreakable. Again, when the mosquito theory of malaria was propounded it was opposed by many who brought against it what they thought to be the unanswerable argument that mosquitos were found in abundance in many nonmalarious regions, all the time unaware of the fact that the culex mosquito was not the malaria-carrying variety, or that the bite even of an anopheline mosquito is innocuous, so far as this disease is concerned, unless the insect has previously charged itself with plasmodia from the blood of a malarial subject.

Arguments of the same nature are now being brought against the vitamine theory of the origin of beriberi. Because the theory was first established in the Far East, where the staple diet of the natives is rice, many have thought that the theory was that the disease could occur only among rice eaters. Others misconceived the theory entirely, thinking it taught that milled rice causes beriberi, totally missing the point that beriberi is a deficiency disease, not due to the action of some substance in the milled rice, but rather to the lack of the vitamine present in the nonpolished grain. The fact is that beriberi is no more and no less dependent upon a diet of rice than upon one of bread. An exclusive diet of white bread and other dishes made from bolted flour will cause beriberi just as readily as one of polished rice. It is not the white flour that causes the disease, but the lack of the vitamines present in the husk of the grain. An exclusive diet of canned foods will sooner or later cause beriberi; it is not any poison in the contents of the cans that causes the disease, but the absence of vitamines which have been destroyed in the process of sterilizing and canning.

These facts are insisted upon by Vedder in his interesting work on "Beriberi,"* and also in an article entitled "Some Further Research on Beriberi," published in the *American Journal of Tropical Diseases and Preventive Medicine* for June of the present year. In the latter he takes up a number of instances of beriberi occurring among prisoners and others not fed on rice and cited by various writers as disproving the rice theory. He admits that it effectually disposes of the rice theory, but shows that the true theory of the nature of beriberi is not a rice theory but a vitamine theory—two very different propositions. A point well brought out by Vedder is that those who report cases which seemingly contradict the vitamine theory are under obligation to state exactly the nature of the diet of those who suffered from beriberi and not simply affirm that it was a "sufficient" diet, or a "rice-free" and "nourishing" diet. A diet of white bread, flour pudding, and canned meat and vegetables is not a "sufficient" diet in the vitamine sense. Another and very important point is that one may live wholly or very largely on the improper diet for a period of ninety days before the symptoms of beriberi become manifest. Accordingly it is not sufficient for the objectors to describe the diet at the time the disease was observed; it is necessary to state what the diet was during several months prior to the outbreak of beriberi.

Vedder's article is interesting not only as an argument in support of the vitamine theory of beriberi, but also as pointing the moral that one should first get a clear idea of a theory before starting out to demolish it.

STAPHYLOCOCCUS INFECTION OF THE RESPIRATORY TRACT IN CHILDREN.

BACTERIOLOGICAL examination of the secretions in catarrhal or inflammatory affections of the upper and lower respiratory tracts in children has shown as a rule the presence of various types of streptococci, such as the *Streptococcus hemolyticus* and the *Streptococcus viridans*, or of the pneumococcus. The staphylococcus has rarely been isolated from these cases. Nevertheless in a period of eighteen months four instances of staphylococcus infection of the respiratory tract occurring in children came under observation in the service of H. Schottmüller in the Eppendorfer Krankenhaus, and are reported in the Festschrift commemorating the twenty-fifth anniversary of the foundation of this institution, in the *Beiträge zur Klinik der Infek-*

*Beriberi, by Edward B. Vedder, M. D., Captain, Medical Corps, U. S. Army. New York, William Wood & Co., 1913.

tionskrankheiten und zur Immunitätsforschung, Vol. III, Nos. 1 and 2. The study of the four cases of what is designated as staphylomycosis of the respiratory tract and lungs shows that this condition presents a typical clinical picture.

This condition which is supposed to be more common than is generally recognized, is in the majority of cases the result of a hematogenous infection, as when a pulmonary abscess is formed secondary to an osteomyelitis. But in the cases reported by Schottmüller the infection came from the outside by way of the upper respiratory tract as was evidenced by the isolation of the micro-organisms from the latter, and by the clinical course of the disease. It appears that children are more susceptible to this type of infection than adults. Most of the cases are fatal, but the conjecture is made that there are many instances of slight or superficial infection which escape observation or whose staphylococcus origin is unsuspected.

When the lung is invaded only one lobe and usually an upper one is affected. Multiple abscess formation, chiefly in the periphery of the lung, results, and there is regularly an involvement of the pleura in the suppurative process. In one of the author's cases the infection penetrated the mediastinum and involved the pericardium. The clinical picture is that of a severe acute illness from the outset, although in one of the cases there was a mild invasion of the disease. The symptoms point to a generalized involvement of the lungs with the rapid accumulation of a pleural exudate. The latter is the chief characteristic of this type of infection. A favorable outcome is to be expected only upon the early recognition of the presence of this pleural exudate and its prompt evacuation. In cases in which the pleural exudate has not yet acquired a purulent character, the demonstration of the presence of the *Staphylococcus aureus* gives an unmistakable clue to the diagnosis. The condition is ushered in by the symptoms of pharyngitis and tracheobronchitis, which are soon masked by these associated with the presence of pus in the pleural cavity. It is easy, particularly if the possibility of staphylomycosis is not borne in mind, to confound the condition with an ordinary pneumonia.

In the treatment, which on the whole has a dismal outlook, the method of aspiration devised by Perthe seems to offer the best results.

FREE FAT AND FASCIA TRANSPLANTATION.

When Kirschner, in 1909, reported his successes in the use of free fascial transplants, many others undertook experiments in this field and it was soon seen that the method gave promise of great usefulness. One of the most interesting of the recent reports of such investigations was that of Von Eberts and Hill (*Surg. Gyn. and Obst.*, March, 1914) who carried out a series of twenty-four operations on dogs, transplanting segments of fascia lata to repair defects in the tendo Achillis, peritoneum, and even in the dura mater. Dural defects were repaired in three instances, two being entirely successful, while the third animal died from edema of the lungs at the end of the operation. In man the method has been successfully employed in bridging tendon defects, in the repair of herniæ, in lesions of the urinary tract, trachea, and elsewhere. In one case of ectopia vesicæ a large area of the transplanted fascia remained exposed and still prompt healing occurred. Kirschner has reported the use of fascial transplants in man in fifty cases of various kinds, practically all with good results, and many others have reported a goodly number of equally successful cases. Fat flaps have had their widest use in arthroplasty and in intraabdominal work; though recently they have been used to advantage in cosmetic surgery also.

Two particularly interesting cases, showing the successful use of each of these tissues, have recently been reported by Tibor Verebély (*Pester Med.-Chir. Presse*, May 24, 1914). In the course of an operation for naso-orbital encephalocele in a three-year-old child, it was found necessary to close a defect the size of a silver gulden in the dura mater. A transplant of fascia lata was used for this purpose, while a flap of the neighboring skin, soft tissues, and cortical portion of underlying bone was sutured over this. The result was entirely satisfactory, the wound healing without complications of any kind. The second case was that of a sixteen-year-old girl who in the course of a few months had developed an enormous hypertrophy of the right breast. The breast, which formed an irregularly shaped mass, hung down upon the abdomen and its weight had resulted in the production of marked lordosis. Verebély made an incision under the breast, shelled out the gland and transplanted in its place three pieces of fat, each about the size of a child's fist, taken from the buttock. This was sufficient to make the right breast correspond in size to the left. Here also primary union was obtained, there were no complications, and the result was eminently satisfactory from a cosmetic standpoint.

These two cases furnished as hard tests of the efficiency of free fat and fascia transplantation as even the most skeptical could wish. The ultimate range of application has not yet been determined and we look for the rapid further development of the procedure.

BIOLOGICAL ASPECTS OF WAR.

The time is long past when there were many who believed with Shelley that

> "War is the statesman's game, the priest's delight,
> The lawyer's jest, the hired assassin's trade—."

Whim or momentary passion can no longer be said to precipitate a nation into a fiendish combat with another. The causes of war are deeply rooted in the laws that direct or the difficulties that beset the evolution of the race. The thoughtful physician whose training in the diagnosis of human ills tempts him to essay the diagnosis of the ills that

afflict the body politic, may look upon the present insensate war, which has burst with such sudden violence upon almost every country of Europe, with keen interest.

According to Lombroso, war is the lineal descendant of crime. Whether or not this view be accepted there can be no doubt that war is frequently based upon criminal aggression, and is always accompanied and followed by an increase in the crimes perpetrated by individuals. But in a larger sense the so-called political causes of war are based upon fundamental racial antagonisms and aspirations. Economic necessity, such as the "law of diminishing returns" in agriculture and the overcrowding of population, may also plunge a nation into the mania of conquest. Apart from these primal causes there are transient but no less potent factors that act as compelling forces in driving an entire people into the throes of conflict. One may speak of national hysteria, of the hypnotic influence of leaders, of the insensate violence of mobs, of the madness resulting from suggestion and imitation, and also of an unreasoning, though perhaps none the less to be respected, national pride.

The physician is interested in war not as a mere spectator but as an active participant. War would be so fearful as to be almost impossible without the ministering arm of the medical profession. It is to be regretted that the very skill which tends to alleviate the horrors of battle is in itself a means of prolonging and rendering more effective its fiendish onslaughts. The ingenuity of the gunsmith, the wizardry of the chemist, the daring of the aviator, are all aided by the learning of the physician and the dexterity of the surgeon. Yet, aside from being an indispensable part of an army, the physician is usually inspired by motives of patriotism. He is thus urged on by a twofold impulse—that of service to his country and that of service to his fellow man.

Second Class Meat.

The lowering of the tariff on meat and other foodstuffs has, for reasons which we cannot discuss here, been followed by a rise instead of a decline in the prices of these articles, and these prices will rise still further in the near future if America is called upon to feed the warring millions of Europe. In view of this and of the fact that every pound of meat that is condemned necessarily adds to the cost of producing meat that is passed, the Department of Agriculture has given permission to the packers to sterilize and cook thoroughly certain classes of meat and sell it in cans or sealed containers, labeled "Second-class, Sterilized." This sterilized cooked meat is the meat of portions of animals the fat of which the old regulations permitted the packers to make into edible lard and tallow. The process of rendering served to sterilize the fat. The new plan extends the same principle so as to utilize the lean portions of this meat which heretofore, because of the presence of certain localized cysts or lesions, packers have not been allowed to sell for food purposes. The meat is of the type which the German and Austrian Governments permit their packers to sterilize and sell in a cooked condition. Under the Department's regulations, in cases where the diseased condition is strictly localized, the unaffected portions of the carcass, which are free from any suspicion of disease, are passed for food and allowed to be sold in the raw state. On the other hand, all carcasses diseased to an extent rendering them unfit for food are condemned. Between these two classes lies the class which may be sterilized under the new regulations. This consists of parts of carcasses believed to be entirely sound, but which come from carcasses affected to a somewhat greater extent than would allow the passing of these parts for food in the raw state, because these parts may contain a chance cyst which, if eaten raw, might lead to tapeworm or other diseases. While the packers of Germany and Austria in this way save a huge waste of meat, it is not known how far the American packers will care to follow the practice, nor how far the American consumer will care to profit by it. At first probably the packers would have to look for their market to the recent immigrants who have been used to this kind of meat in their former homes, and perhaps where the choice must be made between winter vegetables and "second class" meat, even some of our native carnivores may overcome their repugnance to the idea.

The Viability of Stained Preparations of Bacteria.

It has been probably an almost universal belief that the drying, fixing, and staining of a bacterial film on a glass slide resulted in the sterilization of the material which therefore became harmless. The occurrence of three cases of infection, however, in which the cause could be traced to such preparations led Thurn (*Centralbl. f. Bakt.*, 1914, lxxiv, 81) to investigate the subject. He made thin films on glass slides from twenty-four-hour agar cultures, fixing them in the usual way by "passing three times through the flame." He was able after twenty-four hours to get cultures from such preparations of the *Staphylococcus aureus*, typhoid bacillus, colon bacillus, anthrax bacillus, cholera vibrio, diphtheria bacillus, and *Saccharomyces cerevisiæ*. *Staphylococcus aureus* and the anthrax and colon bacilli remained alive even though the slide was kept for twenty-six days in the diffuse daylight of the laboratory. In his study of stained preparations he used in addition to the above organisms the *Micrococcus roseus*, *Sarcina flava*, Friedlander's, Gartner's, and the paratyphoid bacilli, *B. prodigiosus*, *B. fluorescens*, *B. mesentericus*, and *B. vulgaris*, the vibrio Finkler and the *Mycobacterium lacticola*. With the exception of the saccharomyces, none of these organisms was affected by fuchsin or methylene blue after five minutes' application. Only the spore-bearing organisms were able to resist the warm carbolfuchsin stain and all were uniformly killed by treatment with the Gram stain. He was also able to establish that the iodine was the primary bactericidal agent of the Gram stain. It is rather remarkable that such a fact should have for so long escaped observation and it speaks highly for the carefulness of laboratory workers that a larger number of infections have not been traced to this source. Thurn's work deserves wide circulation for it is doubtful if many members of the profession or even laboratory workers themselves realize fully the danger of handling film preparations of bacteria.

Pan-American Surgical and Medical Journal

This is the name of a new journal published in New Orleans, the latest addition to the already long list of American medical periodicals. It is a monthly magazine of the same format as the *Journal of the American Medical Association*, well printed, though the illustrations, largely portraits of the editors and of members of the Louisiana State Society, are not handsome (we mean not handsomely executed), and conducted by Drs. Waldemar T. Richards and Adolph O. Hoefeld, Editors in chief, and Merrick W. Swords, Associate Editor in chief, assisted by a staff numbering one hundred and ninety. It is the official organ of the Louisiana State Medical Society, the Mississippi State Medical Association, the Pan-American Surgical and Medical Association, and the various Parish and County Medical societies of Louisiana and Mississippi. The journal gives promise of being interesting and the editors are to be congratulated on the general good appearance and valuable contents of the first two numbers. There are several things about the paper, however, which strike the reader as rather out of the ordinary. The name is peculiar, reversing the usual order of medical and surgical, thus giving one a little mental jolt whenever the title is read. The first issue, for June, 1914, was called Vol. I, No. 1, but the July issue jumps to Vol. XIX, No. 7. In their salutatory the editors said: "In offering this journal we promise honesty of purpose; we promise truth; we promise a medical journal ethical in every sense. We promise that our advertisements shall be governed by the standard of the American Medical Association." The first three promises are lived up to in the two issues that have thus far appeared, but we fear the last one is shattered beyond repair, for in the second issue more than one-quarter of the advertising space is given over to articles specifically condemned by the Council on Pharmacy and Chemistry and anathema maranatha to the Association *Journal*. Upon the appearance of Vol. I, No. 1, the new periodical was warmly commended by the *Journal of the American Medical Association* for the ethical purity of its business end; we await with interest the latter's comment on the outside pages of Vol. XIX, No. 7.

The Karell Diet.

Karell published an account of his "cure" (a restricted milk diet) before 1892 and in the latter year Hirschfeld pointed out its usefulness in unburdening the circulatory system. The method did not come into common use until Lenhartz revived it in 1908. Strauss and Widal showed that chlorine withdrawal in nephritis was brought about by the Karell diet. A mild form of the latter is useful in elderly sedentary men with subjective sense of abdominal fullness and headache. A loss of up to five pounds in weight relieves the tension of the abdomen. Laxatives and diuretics should also be given along with respiratory exercises. Mild degrees of albuminuria seem to disappear under the same regimen. In the elderly, not over five pounds should be taken off and the patients should rest during the treatment. Hirschfeld, before the Berlin Medical Society, July 1 (*Muenchener medizinische Wochenschrift*, July 7), presented a paper on the Karell cure, which he now prefers to call the underfeeding diet, or as one might term it a starvation cure, since less than one-fourth of the total daily requirement is all that is allowed. The milk cannot be shown to have any specific value as compared with other forms of nutriment. While the Karell diet surpasses other substandard diets, it is not intended for prolonged use. Banting's diet comprised but 1100 daily calories, while in obesity a still smaller daily requirement is sometimes prescribed. The Karell cure is simply a variety of underfeeding.

News of the Week.

Plague in New Orleans.—Two additional cases of bubonic plague were discovered in New Orleans on July 26, making thirteen cases in all since the contagion appeared a month ago. Twelve infected rats have also been found.

Traffic Accidents.—During the month of July twenty-three persons were killed by vehicular traffic on the streets of New York City, making a total of 141 who have lost their lives in this way since January 1 of this year.

New Drug Ordinance.—The New York City Department of Health on July 28 adopted the following ordinance, which is designed to prevent the efforts of the drug users to circumvent the Boylan law by importing cannabis indica: "No cocaine or salts of cocaine, alpha or beta eucaine, either alone or in combination with other substances, or any substance under any other name giving a physiological reaction similar to the physiological reaction of cocaine; and no opium or preparation of opium, and no morphine or salts of morphine, and no cannabis indica or preparations of cannabis indica, or the derivatives of either or any of the substances named herein, shall be held or offered for sale or sold or given away at retail by any person in the city of New York, except upon the written prescription of a duly licensed physician, veterinarian, or dentist. Nothing hereinbefore mentioned, however, shall apply to compounded mixtures containing opium or morphine or cannabis indica or their derivatives for external use only, in the form of liniments, ointments, oleates or plasters."

Health of the Philippines.—Dr. Heiser, Director of the Bureau of Health for the Philippine Islands, in reporting on the employees of the Philippine Government, gives the following statistics: Total number employed, 9,318; Americans, 2,312; Filipinos, 7,006. Deaths: among Americans, 2; among Filipinos, 10. Death rate per 1,000, Americans, 3.51; Filipinos, 5.79. For the month of May the death rate among the residents of the city of Manila was 18.97 per 1,000, which is the lowest rate reached since the American occupation, and is probably much lower than any that has been had during the past one hundred years.

Infant Mortality.—During the week ending July 25, there was a further increase in the infant mortality in New York City, probably as a result of the humid weather. The total deaths of babies under one year of age numbered 294, as against 260 for the preceding week. The number was, however, five less than that of the corresponding week of last year.

Tuberculosis Census.—The National Association for the Study and Prevention of Tuberculosis is planning to collect from the ministers of several thousand parishes through the country statistics as to the number of deaths from tuberculosis in

the parish during the last year, the number of living cases on September 1, the number of deaths from all causes, and the number of members of the parish. The figures will be made the basis of an educational campaign which will culminate in the Fifth Annual Tuberculosis Day to be observed during the week of November 9.

Prof. Paul Reclus.—The death of Prof. Paul Reclus of the department of clinical surgery of the University of Paris, France, was reported on July 29. Dr. Reclus, who was in his sixty-eighth year, was also attending surgeon at the Hotel-Dieu, Paris, an officer of the Legion of Honor, and a member of the French Academy of Medicine.

Personals.—Dr. LEWIS A. SEXTON, for the past six years resident physician at the Willard Parker Hospital, New York, has resigned his position in order to accept the office of assistant superintendent at the Johns Hopkins Hospital, Baltimore. He will fill the vacancy caused by the death of Dr. Rupert Morton and will enter on his new duties on September 1.

Dr. GEORGE E. DE SCHWEINITZ has resigned as ophthalmologist to the Philadelphia General Hospital, and has been appointed consulting ophthalmic surgeon. Dr. Edwin Shumway, formerly assistant ophthalmologist, has been advanced to fill the vacancy.

Dr. JACOB PARSONS SCHAEFFER has been elected professor of anatomy and director of the Daniel Baugh Institute of Anatomy and Biology of the Jefferson Medical College, Philadelphia, in succession to Dr. Edward A. Spitzka, resigned. Dr. Schaeffer was graduated from the University of Pennsylvania in 1907, and since 1913 has been professor of anatomy in the Yale Medical School. An additional gift of $5,000 has recently been made to the institute by Mr. Daniel Baugh, to be used for extensions and improvements.

Dr. JAMES F. DONNELLY, of this city, has been appointed first lieutenant in the Medical Reserve Corps of the United States Army.

Gifts to Charities.—The Nassau Hospital, Mineola, N. Y., receives a bequest of $5,000 by the will of the late Mr. W. Burling Cocks, of New York.

Bowdoin College, Brunswick, Me., has received a gift of $15,000 from the estate of the late Dr. Frank Hartley, of New York, the money to be used for the establishment of a scholarship fund as a memorial to the testator's father, John Fairfield Hartley, of the class of 1829, Bowdoin, and for many years assistant treasurer of the United States.

Sioux Valley Medical Association.—At the nineteenth annual convention of this society, held at Sioux Falls, S. D., on July 23, the following officers were elected: *President*, Dr. Robert Evans, Fort Dodge, Ia.; *Vice-Presidents*, Dr. Julius A. Hohf, Yankton, S. D., and Dr. Charles L. Sherman, Luverne, Minn.; *Secretary*, Dr. George S. Browning, Sioux City, Ia.; *Treasurer*, Dr. Walter R. Brock, Sheldon, Ia.

Obituary Notes.—Dr. CHARLES GARTNER of Brooklyn, N. Y., died at the Lutheran Hospital on July 25 of heart disease. He was a graduate of the Albany Medical College in 1895, and was a member of the Brooklyn Medical Society, the Medical Society of the County of Kings, and the Medical Society of the State of New York.

Dr. CHARLES L. WILLIAMS of Columbus, Ga., a graduate of the Bellevue Hospital Medical College, New York, in 1867, a member and vice-president of the Medical Association of Georgia, and a member of the Muscogee County Medical Society and the Chattahoochee Valley Medical and Surgical Association, died at his home, after a short illness, from dilatation of the heart, on June 16, aged 69 years.

Dr. THEODORE ERSKINE HAMILTON of Springfield, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1861, and surgeon in the Eighth Connecticut Volunteers in 1864 and 1865, died at his home on July 21, aged 80 years.

Dr. CHARLES J. HOLMES of Gaylord, Kan., a graduate of the New York University Medical College in 1868, died at the home of his daughter in Ponca City, Okla., on July 10, aged 71 years.

Dr. THOMAS ARTHUR MCMURTRY of Carthage, Mo., a graduate of the University Medical College of Kansas City, Mo., in 1895, died at his home on July 12, aged 43 years.

Dr. WILLIAM D. BOLLINGER of Lancaster, Pa., a graduate of the Homeopathic Medical College of Pennsylvania, Philadelphia, in 1867, died on July 13, aged 68 years.

Dr. EDWIN J. FARR of Eau Claire, Wis., a graduate of the Castleton Medical College, Castleton, Vt., in 1852, died at his home on July 10, aged 82 years.

Dr. SYLVESTER S. BOGERT, of Pearl River, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1865, a member of the New York State and County Medical Societies, and one of the founders of the East Side Dispensary, New York, having practised in this city until his retirement ten years ago, died at his home from apoplexy, on July 26, aged 70 years.

Dr. JEREMIAH C. WASSEN, of Rhea City, Tenn., a graduate of Vanderbilt University, Medical Department, Nashville, in 1880, died at his home on July 20, aged 78 years.

Dr. JOHN MILTON SINGLETON, of Kansas City, Mo., a graduate of the Kansas City Medical College in 1884, and a member of the Missouri State and Jackson County Medical Societies, died at his home, after a short illness, on July 21, aged 57 years.

Dr. FRANCIS M. BENNITT, of Springfield, Mass., a graduate of the New York Homeopathic Medical College and Hospital in 1883, and a member of the staff of the Wesson Memorial and Wesson Maternity Hospitals, died at his home on July 29, aged 56 years.

Dr. JOHN HENRY GRIFFITH, of Phillipsburg, N. J., a graduate of the Jefferson Medical College, Philadelphia, in 1870, a member of the American Medical Association, the Medical Society of New Jersey, and the Warren County Medical Society, and Mayor of Phillipsburg in 1882 and 1883, died at his home suddenly on July 28, aged 72 years.

Dr. JAMES FOSTER WILSON, of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, 1895, died at his home on July 24, aged 42 years.

Dr. EVAN NORTON, of Conway, S. C., a graduate of the Washington University, School of Medicine, Baltimore, in 1869, and a member of the South Carolina and Spartanburg County Medical Societies, died at his home from pellagra, after a long illness, on July 21, aged 72 years.

Dr. THEODORE ERSKINE HAMILTON, of Springfield, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1861, a surgeon in the Eighth Connecticut Volunteer Infantry during the Civil War, and formerly a member of the staff of the Springfield Hospital, died at his home from cerebral hemorrhage, on July 21, aged 80 years.

Correspondence.

A SIMPLE METHOD FOR CLEANING SLIDES AND COVER-GLASSES.

To the Editor of the Medical Record:

Sir:—Laboratory workers usually experience a lot of bother in cleaning old slides and cover-glasses, particularly old balsam and immersion oil slides. The common method is by boiling with fairly strong alkaline solution, then washing with weak ammonia water or alcohol. The process is tedious, the results uncertain. I have found the following method to be very simple and quite effective. Make solution No. 1:

NaOH solution (40 per cent.) ..... ℥ii
Xylol ..... fl. ℥ii
Alcohol (denatured) ..... fl. ℥ii
NaCl solution (10 per cent.)
q. s. ad fl. ℥vi

Solution No. 2:

HNO_3 ..... ℥i
Alcohol (denatured) ..... ℥iii
Water ..... q. s. ad ℥vi

Each solution is poured into a separate drinking glass and the slides or cover-glasses gently stirred in solution No. 1, two or three times and transferred to solution No. 2, for two or three seconds. Subsequent washing is unnecessary. Mechanically wiping off with a clean towel is all that is required. The glass will be perfectly clean. I have tried the oldest and dirtiest slides I could find, and always with the same good results. In solution No. 1 the xylol is in suspension, therefore the gentle stirring is necessary.

M. Benmosche, M.D.

Nashua, N. H.

OUR LONDON LETTER

(From Our Regular Correspondent.)

PREVENTION OF INSANITY—DEPUTATION TO PRESIDENT OF LOCAL GOVERNMENT BOARD—MR. SAMUEL HERBERT — HIS REPLY — PSYCHOLOGICAL AND OTHER SOCIETIES.

London, July 24, 1914.

The prevention of insanity and its treatment in the early stages as well as that of cases of nervous breakdown likely to lead to the more serious disease has again been brought before the government. A deputation waited on the president of the local Government Board last week and presented a recommendation signed by 236 medical men besides a large number of politicians. This expressed a desire for the provision of greater facilities for the treatment of incipient mental cases without subjecting them to certification. There is so much prejudice both by patients and their families against being certified and retained in asylums—which really tends to aggravate some cases—that it was urged these measures should be restricted to the graver condition in which they have become necessary. For incipient cases the deputation advised preventive treatment should be provided in reception homes and observation wards in special hospitals and poor house infirmaries. To this end the L. G. B. was urged, with a view of preventing the continued spread of insanity, to encourage and enable County and Borough Councils and other local authorities to supply or aid the supply of such institutions which should be subject to the Board's approval and control. Into such homes patients would enter on an absolutely voluntary footing without being certified or subjected to any authorization. Of course they would abide by reasonable regulations while in the institution, but would leave it at any time, though they would be expected to give an agreed notice as in the case of ordinary boarding houses. Unless urgency demanded no patient in such homes should be certified except by an independent doctor and that after leaving the institution certain patients of the class now received in Poor Law Infirmaries for observation and found not to be certifiable, could be accepted in the new homes for proper treatment and would be dealt with on modern hospital lines, as indeed would the private patients. The object aimed at is to prevent people becoming certifiable, but it is most important that the homes should not be looked upon as half-way houses to the asylum. Such a notion would carry on the prejudice against treatment of the mental condition. It is therefore essential that the proposed homes should have no connection with the board of control, whose function is to deal with the mentally deficient who are certified as "of unsound mind." A measure of this kind would probably prevent the increasing spread of lunacy which would be a great gain to the community and check the costly accommodation of our asylums.

Sir J. Jardine told the president of the board that his own experience had shown that many cases of breakdown, owing to overwork, worry, or other causes of impaired health, pass by if properly treated. Something had been done by rest-houses, hospitals, and charities, but the plan proposed would be far more effectual, especially for the poor who cannot obtain rest or change.

Dr. Chapple told what had been accomplished by the Scottish L. G. B. Special wards had been isolated from one of the hospitals. Persons supposed to be perhaps insane were examined in their homes and if there was hope of improvement were recommended for admission without being certified. Last year 1,116 patients were received in this way, of which 330 were cured and 130 improved. Less than half had to go to our asylum.

Dr. Mott urged treatment of mental cases in an institution and deplored the fact that most only obtained treatment when they were chronic. Out of 20,000 cases in the London County asylums half had been inmates for 10 years. In a small hospital being built it was hoped something might be done for the scientific investigation of insanity. In large asylums each patient cannot have as much attention but the object of the State is rather different. The villa system had been good but did not remove the stigma. Mental hospitals would do more than anything.

The president of the board (Mr. S. Herbert) replying admitted the importance of the matter brought before him. As in many things, he said, our Scottish friends were in advance. Legislation had been introduced in 1889, 1890, 1904, and 1905, but the bills differed from the views advocated by the deputation in that the essential feature of their plan was that the board of control was not to have any concern with it. If they required further legislation the prospect of obtaining it was not bright. But he thought much would be done on the proposed lines by administrative action. He would direct the medical department of his board to make a special study of the problem, communicating with L. G. B. of Scotland, the Board of Control, which he knew was sympathetic, and other authorities. Having carefully considered their weighty memorial he

would not hesitate to take administrative steps.

You will not be surprised to learn that the report of this deputation and the reply of the president of the L. G. B. has given rise to a good deal of correspondence in which some conflicting views are expressed, besides which the existing arrangements have been greatly discussed in the newspapers and societies occupied with the questions involved have had their proceedings examined.

On Monday representatives of London Boards of Guardians and others met to consider a paper by Sir William Byrne read at a conference a few weeks ago on the "administration in London of the Mental Deficiency Act." The chairman of the Metropolitan Asylums Board and the Westminster Union presided and was able to say his board was willing to enter into arrangements with the County Council. In fact these bodies have already conferred together and there was every reason to anticipate an agreement such as would be supported by the L. G. B. and the Board of Control. The Asylums Board further hoped the poor law authorities might place some of their accommodation at the disposal of the board so as to prevent unnecessary building. The conference might rely on the cooperation of the Asylums Board to secure the best plan in the interests of the ratepayers as well as of the unfortunate mentally defectives.

The Medico-Psychological Association, an influential body of over 750 medical men interested in questions relating to insanity, its prevention, management, and treatment in asylums or elsewhere, had its annual meeting at Norwich last week. Defects in our present system were acknowledged and suggestions made. A committee which had had the matter under consideration presented its report, which will shortly be in circulation. One of its suggestions is for clinics at general hospitals for nervous and mental cases. Of course such would be on the voluntary system, but it is said powers of detention for a limited period might be granted for certain cases under strictly defined special circumstances.

"The Society for the Early and Non-compulsory Treatment of Nervous Breakdown Apart from Lunacy Administration" announced its formation on Monday. Its spokesmen (two secretaries) declare some measure is required further than those at present adopted to make it possible for patients to be treated in an earlier and more curable stage than those entering asylums. There seems much doubt as to the necessity of a new society. I lean toward the doubters.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

DIMINUTION IN THE BIRTH RATE—ECONOMIC CAUSES—RELATION TO THE DEATH RATE—ANTAGONISM OF PUBLIC AND PERSONAL INTERESTS—MEASURES FOR COUNTERACTING THE EFFECTS OF THE DIMINISHING BIRTH RATE—FAMILY SUBSIDIES—ENCOURAGEMENT OF MARRIAGES—SALE OF CONTRACEPTIVES SHOULD NOT BE PROHIBITED BY LAW.

BERLIN, June 1, 1914.

OF all medical questions none has aroused so much interest in Germany within the past few years as the diminution in the birth rate. The present status of this subject was set forth in an address by Krohne before the German Public Health Society. The maximum birth rate was attained in 1876 when it reached 40.9 per thousand. The rate sank steadily from that time until it reached 28.2 per thousand in 1912. The decrease was most marked in the cities but within recent years it has been also quite pronounced in the country. Such a rapid diminution in the birth rate has not been observed in other countries which are also struggling with this problem. The higher classes particularly have been subject to this decreasing birth rate but within recent years the laboring classes have been similarly affected. The diminished mortality partly offsets the menace of the diminishing birth rate. Since there has been no falling off in the marriage rate and since there has been no increase in venereal disease the cause of the diminishing birth rate must be attributed to certain voluntary practices that are the result of economic stresses, including the industrial employment of women in Germany.

This subject was discussed by Prof. Schlossman before the Society of Medicine. Schlossmann is of the opinion that in the course of time the diminution of the death rate will reach a natural termination. If the death rate in the most favorable years was 16.9 per thousand, then the most favorable limit would be twelve to thirteen per thousand. Since the birth rate would continue to sink the excessive population would get smaller and smaller. The real reason for the diminution of the birth rate lies in the antagonism between the interests of the state which demands as many people as possible, and those of the individual to whom a large number of children brings a certain disadvantage. This antagonism has always existed but is now particularly great because the child becomes productive much later than formerly and the general care of children nowadays costs more than formerly. Since the children begin to earn money later than formerly, and since military service for a time puts an end to this income, the total income of the family is therefore diminished. The provision for cheaper food is an important public question. One means of alleviating the strain on the family treasury when there are many children would be state annuities and the reduction of taxes. Before the same society Prof. Mayet discussed the measures that may bring about an increase of population. He maintained that it is very important to further the welfare of those children that are born rather than to seek to increase the birth rate. On a small scale this has already been accomplished but its general introduction is still far from being achieved. It is important that the health of the mother be conserved during the childbearing period; that illegitimate children should be properly cared for; that the adolescent should be carefully supervised; that marriages should be encouraged, that a campaign should be instituted against the one-child, the two-child, and the childless unions; and that maternity insurance, midwife reform, and the systematic encouragement of maternal nursing be carried out. Homes for friendless women and children should be established. Public parks and playgrounds would further the health of women and children. In the public schools cooking lessons should be given so that women may become better housekeepers. Marriages may be increased by removing the restrictions that now effect women school teachers and office-holders. Venereal disease should be energetically combatted, possibly in time by means of gratuitous treatment.

The Berlin Society of Gynecology has gone on record in favoring the statutes forbidding the sale

of abortifacients but not favoring the laws that prohibit the sale of contraceptives, since this prohibition is regarded as a means of favoring the increase in venereal disease.

1. Ulcerative Angina in Typhoid Fever.—N. B. Potter states that in six to twelve per cent. of the cases of typhoid fever there appear about the same time as the roseola one or more small superficial ulcers, usually upon the anterior pillars of the fauces, constituting the so-called typhoid angina or Bouveret's ulcers. These ulcers may appear sufficiently early to be of some value in the clinical diagnosis of typhoid fever. An appreciation of this lesion will prevent the mistaken diagnosis of syphilis, diphtheria, croup, etc., and of scarlet fever. The ulcers are probably the result of a secondary infection upon a mucous membrane altered by the existing disease. They also occur, but much less frequently, in tuberculosis.

3. Artificial Pneumothorax.—G. M. Balboni points out that success in the use of this method of treatment depends on the manner in which the pneumothorax is produced and maintained. It is best to produce the pneumothorax by large quantities of nitrogen, and to bring it slowly up to the desired volume and pressure. The rapid production of a pneumothorax by large quantities of nitrogen is dangerous as it does not give the adjacent organs time to adjust themselves to the changed conditions; besides the expulsion or sudden evacuation of large quantities of purulent matter may infect the sound lung. The only exception to this is in unilateral hemoptysis where it is desired to control the hemorrhage quickly. It is essential to have a free pleural cavity or one that can be made sufficiently free by subsequent injections to allow complete collapse of the lung. The other organs must be in such a condition as to be able to withstand the extra work thrown upon them. The patient ought to be in a sanatorium under the complete control of the physician. Frequent x-ray examinations are essential for the treatment. Artificial pneumothorax is not an indifferent procedure and should be undertaken only after the careful consideration of each case. The patient should be fully informed that the treatment is long, tedious, troublesome, and expensive and not devoid of dangers.

9. Is Constipation an Evil? W. F. Waugh.

1. Primary Perineorrhaphy by Buried and Subsurface Catgut Suture.—R. L. Dickinson believes that upon buried catgut of small size entire reliance may be placed for pelvic floor repair after labor. This form of suture is even more satisfactory than in secondary operations. In fifty-seven fresh injuries of various degrees, primary union resulted, whether interrupted stitches were closed over by running intercutaneous lacing, or whether a single strand ran as continuous tier suturing and the two ends came together, one submucous, the other subcuticular, the whole secured by one deep knot and one hidden surface knot. The wound is practically invisible from the first. Levator laceration particularly demands tier suture, and anterior fascial gaps are thus best united. The buried layers provide for almost immediate disappearance of the wound, freedom from dressing and stitch drag, skin comfort and skin dryness, and notable swiftness of union. Plain catgut No. 1 does well for all lesser tears, and it may be that it will be found to suffice for all. Chromic gut No. 1 has been employed for about two thirds of the cases. In layer work this has sometimes been used double. Three ways have been tried and found to work well. (1) Interrupted buried stitches, either circular in sweep or of figure-of-eight form. In this method the vaginal portion of the injury may be closed by buried sutures whose knots come just under the surface. Better still, the stitch farthest up the vagina has one end left long, and this becomes a submucous suture. In like manner the stitch nearest the anal angle has an end that works forward, as subcuticular, to meet the vaginal stitch. (2) Continuous layer catgut, in two or three tiers, the last being subsurfaces, the work being done generally with one strand, the larger bights locked by the buttonhole form of stitch. One begins either at the upper end or in the middle, working in both directions with the same strand or several strands. (3) Figure-of-eight, continuous, centerlocking, the same strand going on to make the subsurface closure. Any choice or combination of the foregoing may be used.

2. X-Ray Examination of the Appendix.—J. T. Case notes that in acute appendicitis little need or opportunity for *x*-ray examination will be likely to present itself. Perhaps in doubtful cases, as for instance, suspected left sided appendicitis, a careful injection of the colon with the bismuth clysma under the guidance of the fluorescent screen, followed by careful and intelligent palpation of the abdomen under the screen, may be of some service. In studying chronic appendicitis, however, and its complications and sequelæ, the author believes the Roentgen examination to be capable of rendering valuable service in a large number of cases. Of course when the lumen of the appendix is closed as the result of an obliterative process, bismuth will fail to enter and the appendix shadow will not appear, but in the large percentage of cases in which the appendix shadow can be studied under the fluorescent screen, there are a number of facts capable of demonstration. One may study the size and length of the lumen; the presence or absence of constrictions or links; adhesions; the question of drainage (emptying time) of the appendix; the relation of the visible appendix shadow to a point of pain on pressure; the position of the appendix, whether retrocecal, procecal, etc.

5. Governmental Care and Control of Leprosy.—I. Dyer recommends that the Lafferty bill providing for a national leprosarium should become a law and that the provisions for leprosy isolation should be adequately undertaken at once. The institution of a leper colony should carry with it all of the necessary details for the proper care of the patients as well as for the study of the disease. The cases should be grouped according to their type and stage. Terminal cases should be separated from recently developed cases. An infirmary should care for those with complicating diseases. Single rooms are better than wards, and these should be arranged with ample ventilation—as nearly open air as possible. Frame buildings are more desirable than other structures as they may be easily destroyed or renewed should this be desired. The walls, ceilings, and floors should be of such material as to permit frequent fumigation. Men, women, and children should be separated in any colony provision aiming at final cure. All hospital plans should look out for the provision for bathing facilities, hot water especially. No matter what experimental treatment may finally attain, accepted methods should be systematically followed. The first and most important thing is to have a national asylum established. Then its opportunities should be broadly offered to all students of the disease. The hospital facilities should be of such a character as to attract the leper who wishes treatment and care. The general public should know early that the national leper home is not for compulsory detention but for the care and possible cure of the disease.

6. Treatment of Pericarditis.—R. L. Wilbur states that the accessibility of the pericardium makes local treatment valuable and surgical treatment possible, and leads to the hope that further study may permit the application of remedies directly to the interior of the acutely or chronically inflamed sac. Induced pericarditis in animals offers a good field for study along this line. An early diagnosis of dry or serofibrinous pericarditis permits of the most effective treatment and must be based largely on a vague feeling of oppression in the chest or actual pain, cardiac irritability, and friction rub. Early aspiration, preferably to the left of the nipple-line, is of value in the diagnosis of pericardial effusion, and tapping should be practised when the heart-action is markedly disturbed from apparent increase in intrapericardial pressure. The Brauer method should be more often used in patients giving evidence of pericarditis with adhesions and presenting signs of cardiac hypertrophy or dilatation. It will often diminish disability and often prolong life. Careful attention should be paid to the differentiation of pain in the region of the heart resulting from acute or chronic pericarditis from true angina pectoris, since the prognosis is necessarily so different. Careful and repeated examination for a friction rub should be made over the whole cardiac area in patients with precordial pain.

7. The Abuse of Normal Salt Solution.—L. Litchfield concludes that the administration of any artificial serum as a routine postoperative practice is questionable therapeutics. Too much water may fatally embarrass the heart. Too much salt may fatally embarrass the kidneys. When fluids cannot be taken by the mouth, thirst may be relieved by tap-water or by isotonic dextrose solution given by enteroclysis. The dextrose solution is preferable when there is danger of acidosis and in all cases of inanition. When there is a distinct indication for an artificial addition to the amount of the circulating blood-serum this may best be accomplished by the use of dextrose solution; isotonic (5.1 per cent.) by enterocylsis; isotonic, hypertonic (up to 30 per cent.) or hypotonic (2 per cent.) by intravenous infusion. There are no contraindications to the use of dextrose, but there are often serious contraindications to the use of saline solutions. In all urgent cases the intravenous method is preferable. Greater care should be exercised to see that all water used intravenously is not only sterile but also nontoxic. In medical practice artificial sera should be more frequently employed. Isotonic or hypotonic sera should be used after severe hemorrhage, exhaustive vomiting, or diarrhea; or in cases of extreme inanition. Hypertonic sera should be used in toxemic cases, including eclampsia and uremia; in cases of oliguria with threatened uremia; to combat acidosis; or in toxic states, as after anesthetics, gas, or morphine poisoning, etc. The author regards Fischer's theory of nephritis as a gratuitous hypothesis and his recommendations regarding treatment not justified either by established physiological facts or by clinical experience.

8. Therapy of Cardiovascular Disturbances.—L. H. Newburgh performed an investigation to determine whether the poison of infectious diseases injures the vasomoter mechanism, and to determine whether strychnine and caffeine, both of which are commonly used to stimulate the cardiovascular apparatus, do actually have such an effect. He notes that since the blood pressure is not low either in persons showing grave symptoms of pneumonia or in those dying of that disease, and since it has been proved that the vasomotor arcs are normal in animals near death from pneumonia, it is logical to conclude that the vasomotor mechanism is not impaired in pneumonia. The author believes that strychnine does not improve or augment the work of the heart in persons suffering from broken cardiac compensation. It could not be shown that either strychnine or caffeine stimulated the cardiovascular apparatus in any of the conditions studied.

9. Cholesterinized and Non-Cholesterinized Artificial Antigens in the Wassermann Reaction.—C. C. W. Judd finds that standard cholesterinized antigen does not yield an appreciable number of non-specific reactions. Standard cholesterinized antigen detects many luetic cases which do not yield positive results with Noguchi antigen. Standard cholesterinized antigen, though amenable to the influence of treatment, is less susceptible to extinction by therapeutic measures. Standard cholesterinized antigen possesses splendid keeping properties, is always available, and is easy of preparation. It is an ideal artificial antigen.

10. The Suprarenals and the Pulse-Rate.—R. G. Hoskins and C. R. Lovellette states as the result of his experiments performed upon dogs that intravenous injections of suprarenal extract under conditions closely simulating suprarenal discharge cause not only an increased blood-pressure but generally also an accelerated

pulse. Acceleration of the pulse, therefore, is one of the adaptive functions of the suprarenal glands.

11. **The Time That the Breath Can be Held as an Index of Acidosis.**—Yandell Henderson believes that such an index of the degree of acidosis is afforded by the length of time that the breath can be held voluntarily. The point of view now coming to be accepted regarding the relation of acidosis to the rate of pulmonary ventilation and the alveolar carbon dioxide is based to a considerable extent on data accumulated by the Pike's Peak expedition. During a stay at the summit and after the descent the author and his associates had frequent occasion to note that the length of time the breath could be held was shorter as the alveolar carbon dioxide was lower, that is, according to the intensity of the acidosis which causes the increased respiration of great altitudes. The relation was not, however, a direct proportion. While the alveolar carbon dioxide was reduced about one-third most of the members of the party could hold their breath for less than half as long as at sea-level.

1. **Prognosis.**—W. Hale White quotes Hippocrates who said: "The best physician is the one who is able to establish a prognosis." In tuberculosis anorexia, vomiting, and diarrhea are very bad signs, especially if persistent; indeed, loss of weight from any cause is bad. A persistently rapid pulse, continued pyrexia, and frequent profuse sweats are all bad, but it is surprising how some of these symptoms may persist for a long time, and yet return to normal. In heart disease, generally speaking, the louder the murmur the better, for it means that owing to the vigor of the cardiac muscle the blood is being sent forcibly through the diseased valve. An irregular pulse is not so often of bad prognostic significance as a rapid one. In lobar pneumonia a most important circumstance is the age of the patient. Pneumonia is chiefly fatal by the action of the toxin on the heart; a very rapid feeble pulse of poor volume is always very serious. If sufferers from pneumonia sleep badly they do as a rule badly, and if they sweat much apart from the crisis they do badly, probably because the sweating indicates severe infection. An important circumstance in the prognosis of chronic interstitial nephritis is the age of the patient. Young subjects with chronic granular kidney rarely if ever do well, and almost anyone under 30 who has it will soon die. The sufferer from this disease who complains of general weakness does badly, so does the patient who is thin and pale, and if a patient takes to bed because of weakness he will not live long. In cerebral hemorrhage the following point to a fatal result: (a) Coma still present at the end of 24 hours; (b) Cheyne-Stokes breathing as a result of the hemorrhage; (c) much mucus in the lungs; (d) paralysis of all four limbs; (e) a very low temperature; and (f) a very high temperature. Diabetes is a disease of great interest from the viewpoint of prognosis. In the first place it is a racial disease, being terribly common among the natives of India; it is commoner in Jews than in Christians. Quite apart from race, however, it is a family disease. The most important thing about the prognosis of diabetes is the effect of treatment; it is possible to know beforehand whether a patient is going to respond easily to this. The other important thing is whether the sufferer is going to live in easy and comfortable circumstances. One cannot possibly tell whether a treatment is good or bad unless one knows what the natural course of the disease is. A study of life insurance statistics clearly shows that the mortality from any disease increases in proportion as the abdominal girth of the patient over that of the expanded chest increases. It is well known that overindulgence in alcohol greatly damages the prognosis in any disease. Lastly, there is the mental factor: every doctor dislikes the patient with an acute illness who is sure he will die, and likes the patient who is certain he will recover.

3. **Hemorrhagic Typhoid Fever.**—A. Caddy and B. Molony report three cases of typhoid fever which came under their observation in Calcutta, two of which cases developed very unusual symptoms. In the first case during the course of the fever there occurred an extensive purpuric eruption, which was followed by a generalized bleeding from the mucous membranes—viz., the tongue, gums, bladder, and intestines. In the second case hematemesis occurred while the fever was at its height. This happened on three occasions, together with bleeding from the bowel. The third case was one of intestinal hemorrhage complicating typhoid fever and ending in recovery. In each case the patient was given a course of quinine, although it is very uncommon for Europeans living in the English quarter of Calcutta to get infected by malaria. This quinine treatment in cases which eventually prove to be typhoid often seems to aggravate the disease. As regards purpura complicating typhoid fever and hemorrhagic typhoid fever the authors have been able to find very few references in current literature. In discussing the question of treatment of these cases (other than dieting and nursing) one must think of them as examples of two different types of hemorrhage as it occurs in the course of typhoid fever—viz., (1) hemorrhage due to widespread damage of the vessels in different parts of the body; and (2) hemorrhage due to gross damage by ulceration to one or more vessels in the gut. To stop the bleeding the first essential is to rest the bleeding part. This may be obtained by the administration of opium. The coagulability of the blood may be increased by giving calcium salts. In all future cases the authors would use emetine hydrochloride as advocated by Low. To make up for loss of body fluids it seems logical that one should transfuse the cases of the second type; hypertonic saline, as likely to help in increasing the coagulability of the blood, would be the fluid of choice.

1. **Diathesis in Infancy.**—H. C. Cameron states that the exudative diathesis of Czerny is so common that its manifestations in greater or less degree are met with every day in practice and are familiar to all. In early infancy the most common way in which the inheritance

shows itself is the complete or relative failure of breast-feeding. The children often show none of the strength, vigor, and firmness of the normal breast-fed baby. From the first they may be meager, small, and complaining, and persistently dyspeptic. The mother's breasts may be well formed and full of milk, and yet for weeks and even months no improvement takes place. Dyspepsia, with the passage of green stools and vomiting, is frequent, and in a breast-fed child should always suggest the existence of this diathesis. In other cases, however, a different picture presents itself. The infant achieves a rapid rise in weight, yet the more rapid the growth the more marked do the other symptoms of the exudative diathesis become. Finkelstein has emphasized especially the tendency for infants who show the diathesis to belong to one or other of these two types; the thin and wasted type; or the fat, pasty, and eczematous type. Seborrhea of the scalp is extremely common. A dry eczema of the cheeks and chin is common especially in thin infants. Urticaria papulata is often seen and intertrigo occurs readily. Nasopharyngeal catarrh, with the accumulation of secretion in the posterior nares and glands is common. Laryngitis, bronchitis, and otitis media are frequent complications. The lingua geographica, eczematous or phlyctenular conjunctivitis, and circular caries of the teeth are seen in later infancy. The mucous membrane of the intestine is also affected. In earliest infancy constipation or dyspeptic green stools are common symptoms. The spleen, thymus, tonsils, lymphatic glands and intestinal follicles all show a tendency to enlargement which is probably secondary to the chronic irritation in the areas which they drain. The symptoms of the diathesis are encouraged or controlled largely by the composition of the diet. Especially marked as a rule is the ill effect of a fat rich diet, such as cow's milk. Even the breast milk may disagree for this reason. Limitation of the amount of milk and the early substitution in part of carbohydrate food is usually the most successful line of treatment. Without dietetic regulations the local treatment of the various manifestations, the repeated catarrhs, of the lymphoid overgrowth—as, for example, the adenoid enlargement—is often without avail. Overfeeding, Cameron says, is especially harmful, and the food should be reduced so that it just covers the physiological needs.

1. Some Problems in Cardiac Physiology.—A. F. Stanley Kent notes that cases have occurred in which an interruption of the normal rhythm of the heart has been observed, although the auriculoventricular bundle has been proved to be intact, and cases of normal rhythm have occurred in which the bundle was subsequently found to be destroyed. In 1892 the author described the existence of an additional muscular connection between the auricle and ventricle in the right lateral wall of the heart. Recent histological investigations by the author have shown that there exist in the heart, in the neighborhood of the auriculoventricular groove on the left side of the organ, neuromuscular structures whose constituents are partly nervous and partly muscular, and these have connections with the nervous structures of the groove and with the muscular tissue of the auricle and of the ventricle. There exists in the right lateral wall of the heart a mass of hitherto undescribed nodal tissue. In association with the latter there exists at least one muscular path between auricle and ventricle along which impulses can pass, and which is able to keep the chambers in physiological association, even when the auriculoventricular bundle has been cut. Experimental results have been obtained which completely bear out the anatomical fact of the existence of an additional muscular path between auricle and ventricle.

2. Goiter, Edemic and Exophthalmic.—R. Farrant records observations made between 1909 and 1914 on 85 cases of goiter (exclusive of simple hyperthyroidism) concerning the relationship between toxemias and diseases of the thyroid. He sought to prove that in cases in which the thyroid is diseased the causative microorganism or toxemia can be determined and to show that in this way diseases of the thyroid cannot only be cured but also prevented. Endemic goiter is caused by the toxins from the atypical forms of *B. coli*. The mutants are usually conveyed by water. They become indigenous in the intestine, and different mutants of *B. coli* are to be found in the feces of cases of endemic goiter. The mutants set up an apyrexial toxemia which stimulates the thyroid, leading to a colloid hyperplasia and eventually to enlargement of the gland. The whole process can be imitated in the laboratory, and endemic goiter can be induced in guinea-pigs by feeding it with small doses of the mutants. The supervention of a fresh toxemia while the gland is in a hyperactive state causes a complete hyperplasia, with absorption of colloid and signs of hyperthyroidism up to a condition of exophthalmic goiter. This is dependent on the intensity and duration of the fresh toxemia. Endemic goiter is preventable by the avoidance of water contamination and by the sterilization of contaminated water. It can be cured by the administration of intestinal antiseptics and the gland returns to normal, providing no degeneration has taken place. The gland as a whole involutes to normal, but the adenomata or cysts are left. A condition similar to endemic goiter can be caused by other toxemias capable of inducing a colloid hyperplasia. Exophthalmic goiter is due to a combination of toxemias of an intensity sufficient to cause a hyperplasia with absorption of the colloid material. One acts during a period sufficient to give rise to a complete hyperplasia associated perhaps with slightly marked signs of hyperthyroidism without necessarily any glandular enlargement. The supervention of another infection stimulates the gland, which usually enlarges, and the signs of hyperthyroidism become very evident; the case develops into one of typical exophthalmic goiter. A nervous shock may suggest the diagnosis by suddenly bringing into evidence the symptoms of hyperthyroidism, especially those connected with the nervous system. The severity and duration of exophthalmic goiter are dependent on the intensity and duration of the toxemias. If they are of short duration the disease will disappear in a few months. Exophthalmic goiter can be prevented by the detection of the early cases of hyperthyroidism and the consequent removal of the basal toxemia. It can be cured, Farrant holds, if the causative agents are removed before degeneration has occurred either in the gland or in those organs that are affected by the hypersecretion.

Paravertebral Conduction Anesthesia.—Siegel, an assistant of Krönig, after duly recognizing the work of Crile in nerve block (the Germans are all too slow in this respect, believing apparently that Crile uses the simple conduction technique) gives his results with paravertebral anesthesia in gynecology. The method resembles that of parasacral anesthesia applied to the lumbar vertebræ, each spinal nerve being anesthetized just as it leaves the foramen. The author employed it in 170 cases and in 70 per cent. of these no inhalation narcosis was superadded. Of the 170 cases 20 were obstetrical, the rest gynecological. The term paravertebral does not exclude parasacral, for the sacral nerves were also anesthetized, either *per se* or in combination with the lumbar nerves. The "twilight sleep' so freely practised in Krönig's clinic was employed to exclude the psychic trauma, serpolamin and narcophin being employed for the purpose. Crile is given credit for this idea. The author admits that his 170 cases are too few to establish a new induction, but is entirely satisfied with them as they stand. The range of intervention is the same as in intraspinal anesthesia.

Clinical Notes on Strophanthus.—Johannessohn and Schaechtl refer to the uncertainty of strophanthin when given per os because of the possible injury sustained from the digestive fluids. It was learned by experiment that pepsin and pancreatin were inert, but the acidity and alkalinity of the juices were alike able to weaken the action of strophanthin. It is known that there are several forms of the drug, characterized by letter prefixes, and that these have different behavior in regard to digestive fluids. The so-called g-strophanthin of Thom has the action of strophanthin, but may be given in larger doses (intravenous dose double; daily dose by mouth three or four fold greater). Given per os in this form it acts more promptly than digitalis, and produces an unusually profuse diuresis in cases of ascites and edema. In vitro this strophanthin cannot be attacked by any of the digestive fluids, acid or alkaline. There is much less tendency to cumulation than when digitalis is used. These attempts to equal or surpass the virtues of digitalis per os are doubtless due to the superior quality of strophanthin when given intravenously.

Double Perforation of a Tuberculous Nodule into the Aorta and Bifurcation of the Trachea.—Girardet relates a case of an accident which might in theory be more frequent than literature warrants, when we consider that the tracheobronchial glands are more frequently the seat of tuberculosis than any other one structure. Perforation of the aorta *per se* is not of such extreme rarity because this is one of the readiest explanations of acute miliary tuberculosis, the original focus being the tracheobronchial glands. Softened glands also rupture into the lower portion of the trachea. The double perforation, however, seems to have been reported but once before, as far as complete conformity with the author's case; but cases more or less resembling the author's in which the tuberculous focus made two openings.

Münchener medizinische Wochenschrift.

July 7, 1914.

Anesthesia of the Uterus.—Kraus implies that local anesthesia is but a stepmother to the uterus. The first attempts were directed to the cervix and parametria, while Sellheim obtained superior results with conduction anesthesia. The author believes he has made a further advance by employing pressure anesthesia, so well known to the dentists. The stretching of the cervix is a painful operation. The operator inserts into the cervix rods of cocoa butter, which contain the proper content of novocain—suprarenin. These can be pressed quite up to the fundus, after which they melt and the entire mucosa is rendered anesthetic. Hegar's dilator is then introduced. To improve the asepsis the latter was coated with melted cocoa butter containing the anesthetic and the whole, after the butter had hardened, pushed into the cervix. The first results were imperfect and instead of cocoa butter a syrup containing the anesthetics was substituted. The syrup was boiled and allowed to congeal on the dilator. Thus far asepsis and anesthesia have been assured. The author has operated upon 24 cases of endometritis (curettage) with the above anesthesia, with satisfactory results.

Hysterical Dermatoses.—Antoni refers rather to the relationship between these affections and perhaps to their coincidence in the same subject, because naturally an hysterical woman can suffer from any dermatosis. Since peculiar affections occur in hysteria which can hardly be artefacts but psychogenic dermatoses, there are, however, others which are readily recognized as artefacts. These smack of simulation and are recognized chiefly by their traumatic nature and by their limitation to areas accessible to the finger nails. The author relates a case of difficult diagnosis in a young woman, in which an ulcerous condition, suggesting either tuberculosis or syphilis, covered the entire abdomen. These ulcers had been treated in every conceivable way, including transplantation, but to no avail. The sores were markedly serpiginous and fetid. A few had healed with marked scarring; while in other cases sloughing areas were present. The WaR was negative, but the patient had evidently been treated with salvarsan at some period as shown by the scars following intravenous injection. There was a history of hysterical attacks and of many other phenomena suggesting hysteria, occurring especially in the skin—recurrent erysipelas, spontaneously appearing and healing sores, profuse sweating, dryness of skin, etc. At 14 she had pus in the abdomen, requiring laparotomy and healing perfectly. Six years later she fell and ruptured the scar, suppuration followed and then ulceration. The condition had gradually spread. After reviewing the case a watch was set upon the patient, and it was learned that while supposedly asleep the patient had leaned upon a hot stove, thereby causing bullæ and eventually the severe condition described. The snap diagnosis before the watch was artefacts produced by hot water.

Double Intranasal Dacryocystotomy for Lachrymal Disease.—D. R. Paterson reports the case of a girl aged 16 years. "Watering" of both eyes noticed for three years. She had been treated two years ago for atrophic rhinitis, which was still present. About five weeks before admission a phlegmon appeared over the left lachrymal sac with the formation of an abscess or fistula. On the right side there was a blenorrhea of the sac, a quantity of thin pus being evacuated on pressure. West's operation of opening the sac from the interior of the nose was done on both sides. On the right side the sac wall was overlapped by an affected ethmoidal cell, which was opened up; on the left it was necessary to resect the upper part of the septum in order to get room. The result of the operation was immediate and the fistula closed. The case illustrates (a) some conditions of the tear-sac brought about by stenosis, viz., blenorrhea of the sac, dacryocystitis, phlegmon, and fistula, and their dependence often upon a nasal affection; (b) the intranasal conditions usually met with in the operation; and (c) the advantages of the intranasal route to the lachrymal sac. —*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE INADVISABILITY OF INSTRUMENTAL EXAMINATIONS FOR LIFE INSURANCE.

It is difficult for the members of the field force to understand why the making of an instrumental examination by a physician serving as a medical representative of a company is inadvisable, even though the report of the regular examination happens to be incomplete without the information that could be gained by a resort to some such procedure. The objections to instrumental examinations may be considered from two points of view:

1. The natural reluctance of corporations, companies, or associations to allow or countenance any procedure which might afford an opportunity for the institution of one of the many legal claims for damages that arise without foundation or upon slight provocation. They realize from past experience that they have small chance for justice from the average jury. Life insurance companies are erroneously regarded in the same light as great money-making corporations and the fact that the policyholders must pay the bill when a company is mulcted, is forgotten. A disgruntled applicant, through this unfortunate condition in the courts of justice, has the power to inflict unfair expense, trouble, and annoyance upon a company by instigating a suit for damage claimed to be the result of an instrumental examination, the damage being feigned or imaginary.

2. The instrumental examination is usually one which requires the experience of a specialist, and actual injury may be inflicted through carelessness or the unpractised hand of an examiner. The harm done would rarely be more than one of slight degree, but would, nevertheless, afford an opportunity for an unscrupulous lawyer to impress a jury, already inclined to favor the individual.

Whenever, then, an instrumental examination is needed to complete the physical examination, the applicant should be requested to furnish a certificate covering the point in question from his attending physician or from a competent authority. If he is unwilling to assume the responsibility, the risk should be postponed until this requirement is fulfilled.

Some of the important instrumental examinations may be cited as follows:

Passing urethral sounds. This is a delicate operation, especially if there happens to be an obstruction. The procedure is fraught with danger of damage to the tissues unless conducted by one familiar with every detail.

Rectal examination. This procedure is required in some cases of anal and rectal trouble and should be carried out more often than has been the practice, instead of assuming that hemorrhoids is the sole cause for the disturbance. Malignant growths, tuberculosis, fissures, fistulas, and ulcerations will be revealed occasionally by an instrumental examination, when the milder condition only has been supposed to exist. An examination of the prostate is necessary at times in men past middle life. Moderate hypertrophy of this gland will only be appreciated by one who has constant practice in this line of work.

A section of a tumor or growth, or the removal of fluid may be desired for pathological examination. Blood tests are called for by some companies when there is a history of syphilis, a process which necessitates the withdrawal of a considerable quantity of blood.

The examinations of the larynx, nasopharynx, and middle ear require the services of specialists in order to obtain a report of value. The instrumental examination of these parts should be carried out by specialists for the purpose of obtaining reliable information as well as for the object of guarding the company against the liability of accidents.

What Significance Should Be Imputed to Smoking in Estimating the Duration of Life?—In the theory of life insurance there is no concern as to smoking or nonsmoking. As a rule there is no question about smoking upon the application blank. Nevertheless in the individual case the prognosis as to the use of tobacco often plays a serious rôle, when the examiner finds something which might represent the action of nicotine.

The point of view varies much, some regarding tobacco as a race poison from all angles, while others look upon it as harmless when used in moderation. Among the former are those, for example, who ascribe the downfall of the Spanish race to incessant smoking.

We know that millions of men use tobacco without suffering any apparent harm. On the other hand we frequently encounter cases of tobacco poisoning due to abuse of smoking. Individuals react in different forms to the latter. One complains of headache and vertigo; another is anemic; a third is nervous, irritable, and soon fatigued; a fourth has a tobacco heart; a fifth has amblyopia, etc., etc. Especially pronounced are the effects of the drug when smoked in cigarettes in childhood. Hence it is not only the quantity smoked, but the individual reaction which must be considered. In this regard tobacco ranks with alcohol and coffee.

We should not discuss the ill effects of tobacco alone, but also the smoker. He may use spirits or drugs, or may be subject to business cares which are aggravated by oversmoking.

Finally tobacco is one of the great creature comforts, acting, according to circumstances, as a sedative or stimulant to the mind and with little influence on the emotional sphere. No serious attempt is made to calculate any alterations of the expectation of life due to tobacco.—*Blätter für Vertrauensärzte der Lebensversicherung*, May-June, 1914.

Life Insurance and Aortic Disease.—At the meeting of the British Life Assurance Medical Officers' Association held on November 5, 1913, aortic disease in relation to life insurance was discussed. Dr. F. de Haviland Hall thought that the essence of the matter was as to whether the case was one of of rheumatic origin or not. He pointed out that a case of aortic disease of rheumatic origin was very different from that due to some degenerative change. Whether one was justified in recommending a man with aortic regurgitation for life insurance was a difficult point. It certainly should not be done if the regurgitation came on after the age of 40. If due to rheumatic fever, and ten or fifteen years had elapsed since the onset of the attack, then he thought the case might possibly be accepted with a considerable addition. Dr. Hector Mackenzie said that he had always followed the rule of rejecting cases of aortic regurgitation.

Book Reviews.

LE LABORATOIRE DU PRATICIEN. Analyse Clinique, Méthodes et Procédés. Par PAUL GASTOU, Chef du Laboratoire Central et de Radiologie de l'Hôpital Saint Louis. Avec 18 planches contenant 319 figures en noir et couleurs par LOUIS NICLET, Dessinateur Photographe du Laboratoire Central de l'Hôpital Saint Louis. Price, 4 francs. Paris: A. Poinat, 1914.

THIS is the third portion of Gastou's work on laboratory diagnostic methods, the previous sections of which have already been noticed in these columns. It is devoted to the study of the urine, the feces, and the other secretions and excretions, the preparation and examination of sections of tissues, and the serodiagnostic methods. The use of darkfield illumination in the investigation of urinary sediments and other body fluids with the microscope is described at much greater length than is usual, and many of the drawings are of objects viewed by this method. The text is necessarily very condensed owing to the limitations of space which the author has imposed on himself, so that the work can never be regarded as more than supplementary to the larger books on the subject, but it does contain much that is of value and will be found of interest by those who do a great deal of laboratory work.

A TREATISE ON CLINICAL MEDICINE. By WILLIAM HANNA THOMSON, M.D., LL.D., Physician to the Roosevelt Hospital; Consulting Physician to the New York State Manhattan Hospitals for the Insane, and to the New York Red Cross Hospitals; formerly Professor of the Practice of Medicine and of Diseases of the Nervous System in the New York University Medical College; Ex-President of the New York Academy of Medicine, etc. Price, $5.00. Philadelphia and London: W. B. Saunders Company, 1914.

THE striking feature of this work is its originality. The author presents the results of observations gained in an extensive private and hospital practice. There are certain subjects about which his writings are now well known. Of these subjects, to which ample attention is given in this volume, may be mentioned the following: The mechanism of surface chill or "catching cold," infections by the *Bacillus coli*, and exophthalmic goiter. A special chapter is devoted to a consideration of common but important symptoms such as pain, emaciation, cough, dyspnea, edema, and vomiting. In the treatment of bronchitis the author extols the value of an emulsion of linseed oil made up in an elaborate formula with demulcents and aromatic oils. A most interesting and valuable account is given of mucous colitis in which in addition to topical remedies the author has demonstrated the value of small alterative doses of castor oil. In discussing this subject the author shows that he is no apostle of therapeutic nihilism even in the presence of a condition which is usually intractable and often incurable. Throughout this volume the same attitude is maintained. The mature judgment of a clinician of rich experience is recorded for the benefit of those whose opportunities have been more limited. For this reason the present volume stands as one of the most signal contributions to medical literature within recent years.

RADIUM AND RADIUMTHERAPY. Radium, Thorium, and other Radio-Active Elements in Medicine and Surgery. By WILLIAM S. NEWCOMET, M.D., professor of Röentgenology and radiology, Temple University, Medical Department; physician to the American Oncologic Hospital; fellow of the College of Physicians, Philadelphia. Illustrated with 71 engravings. Price, $2 25. Philadelphia and New York: Lea and Febiger, 1914.

THE writer of this volume has compiled a work which contains a good deal of value though there is much in it which will not interest the physician. Elaborate pictures of apparatus are given, without sufficient description to enable one who is not a physicist to understand the method of employing them. The ideas expressed concerning the use of screens are rather antiquated, and several of the photomicrographs intended to show sections from malignant tumors are not at all convincing. Much of the clinical material is quoted from the work of others without sufficient criticism and some of the cases thus included from the literature are distinctly misleading. As it is becoming more and more evident that radium has but a narrow range of action and is not applicable, in the quantities and methods now available, for the treatment of any but relatively benign carcinomata, positive reports of cures must rest on a scientific basis and can not be accepted unless the diagnosis has been confirmed by the microscope and the patient has been under observation for at least three years. Despite its defects the volume forms a useful compend of current English and American literature; unfortunately the recent German work has been neglected.

GEBURTSHILFLICH-GYNÄKOLOGISCHE PROPÄDEUTIK. Eine theoretische und praktische Einführung in die Klinik und in die Untersuchungskurse. Von Prof. Dr. OSCAR POLANO, Oberarzt an der königlichen Universitäts-Frauenklinik Würzburg. (A Manual of Gynecological and Obstetrical Methods of Examination). Mit 78 meist farbigen Abbildungen. Würzburg: Curt Kabitzsch, 1914.

THIS exceedingly well written manual by the well-known Bavarian obstetrician, Polano, is unfortunately supplied with a title, the meaning of which very few will recognize. It comprises a theoretical and practical introduction to clinical methods of examination in gynecology and obstetrics, based entirely on normal conditions; for as the author truly claims, it is only by an exact knowledge of the normal that pathological changes may be recognized. In the first part of the work the anatomy and biology of the female genitals are discussed and in the second or practical portion, the general methods of examination for obstetrical and gynecological purposes are described. The author refers to all the well-known and even more recent methods of examination and a number of clear and satisfactory illustrations are employed to illustrate the text. The book constitutes an excellent manual for the student and is worthy of the attention of the profession.

MENTAL DEFICIENCY (Amentia). By A. F. TREDGOLD, L.R.C.P., Lond., M.R C.S., Eng. Consulting physician to the National Association for the Feeble-Minded, and to the Littleton Home for Defective Children; Lecturer at the Medical Graduates College, London; formerly Medical Expert to the Royal Commission on the Feeble-Minded; Research Scholar in Insanity and Neuropathology of the London County Council and Assistant in the Claybury Pathological Laboratory; late Resident Clinical Assistant in the Northumberland Asylum, etc. Second Edition Revised and Enlarged Price, $4.25. New York: William Wood & Co., 1914.

THIS second edition of the work has been thoroughly revised, many chapters have been entirely rewritten, and a new one added dealing with the mental tests and case taking. The chief plan and purpose of the book are the same as in the first edition. It regards the incidents, causation, pathology, mental and physical characteristics, social relationship, diagnosis, prognosis, and treatment of persons suffering from mental deficiency. Numerous case histories illustrate the points in the text. There is an extremely interesting list of eighteen tables, chiefly of comparative values. Twenty-nine illustrations portraying patients belonging to the defective class enhance the value of the description.

FIRST AID DENTISTRY. By E. P. R. RYAN, First Lieutenant, Dental Surgeon, U. S. Army. With eighty illustrations. Price, $1.25. Philadelphia: P. Blakiston's Son & Co., 1914.

As set forth in the preface, "this book has been designed for medical and dental practitioners and students; for nurses; and especially for hospital corps men of the military and naval service and for all who are called upon to administer relief from dental pain, where the services of a dental surgeon cannot be obtained" The subject matter is dealt with under the following headings: septic conditions of the mouth; salivary deposits; inflammation of the mucous membrane of the mouth; syphilis in the mouth; brief dental anatomy; dental pain; the treatment of pulpitis; the treatment of putrescent pulp and non-septic pericementitis; the treatment of abscesses; neuralgia; pyorrhea alveolaris; fractures and dislocations of the jaws and their treatment; dental extractions; postoperative conditions; and diseases of the maxillary sinus. There are a large number of excellent illustrations and many useful formulas. As an aid to the general practitioner who may be called upon at times to render first aid dental work this book supplies a distinct want.

How to Diagnose Smallpox. A Guide for General Practitioners, Post-Graduate Students, and Others. By W. McC. Wanklyn, Assistant Medical Officer of the London County Council, and Formerly Medical Superintendent of the River Ambulance Service (Smallpox) of the Metropolitan Asylums Board. With Illustrations. Price, $1.50 net. New York: Paul B. Hoeber, 1914.

The importance of the subject matter of this book cannot be exaggerated. In 1902, of the 7,842 cases which were certified in London as smallpox and sent to the Receiving Stations 607 were found not to be smallpox and included such cases as scarlet fever, syphilis, typhoid fever, erysipelas, meningitis, pyemia, purpura, psoriasis, scabies, acne, furunculosis, etc. Of the incorrect diagnoses one-third were diagnosed as chickenpox. An extensive experience dealing with the care of smallpox cases over a period of twenty years enables the author to furnish a lucid account of the difficulties with which the diagnosis of smallpox is beset. He believes that the data for the correct diagnosis are available in nearly every case of smallpox. The subject matter of this volume is as follows: the effect of unrecognized cases in spreading smallpox; methods of clinical examination; a description of typical cases of smallpox, with special reference to the arrangement of the rash upon the skin; an explanation of the principle underlying that arrangement; other diagnostic features of smallpox; the initial rashes; the differential diagnosis of chickenpox, measles, and other exanthems. There are four full page plates illustrating the typical eruption in smallpox and two plates showing the characteristics of chickenpox. There are also a number of diagrams showing the petechial initial rash of smallpox, and one diagram illustrating dusky erythema and hemorrhagic smallpox. The book is handsomely printed and should prove of distinct service to the student and practitioner.

Transactions of the American Pediatric Society, Twenty-Fifth Session. Held at the New Willard Hotel, Washington, D. C., May 5, 6 and 7, 1913. Edited by Linnaeus Edford La Fetra, M.D. Volume XXV.

As in the case of the preceding volumes of transactions of the American Pediatric Society the present volume reflects the progress of pediatrics in this country. This is clearly shown by an enumeration of some of the articles as follows: whooping-cough: a plea for more efficient public regulations relative to the control of this most serious and fatal disease, by J. L. Morse, the diagnosis and treatment of pyelitis in infancy, by R. G. Freeman; cases of pancreatic insufficiency in children, by L. Porter; a new and rapid method for the estimation of total fats in infants' stools, by D. M. Cowie and W. S. Hubbard; is diphtheria frequently a bacteremia? by M. Nicoll, Jr., and H. L. Wilcox; the ammonical diaper and its correction, by T. S. Southworth; duodenal ulcers in infancy, by L. E. Holt; casein in infant feeding—experiments in exact percentages, by H. I. Bowditch and A. W. Bosworth; acute infectious jaundice in children, by C. Herrman; the relation of the physcian to social service, by J. C. Gittings; a case of bilateral hydroureter—chronic pyocyaneous infection, by H. Heiman; cases of edema in infants, by H. D. Chapin; three types of occlusion of the esophagus in early life, by T. M. Rotch; parotitis complicated with meningitis, by G. N. Acker; tumor of the cerebellum, by S. S. Adams; studies in cardiac stimulants, by W. P. Lucas; studies on the incubation period, No. 1, serum disease, by D. M. Cowie; acid intoxication in children, by I. A. Abt, and acute lymphatic leucemia, by I. M. Snow.

Geburten-Rückgang und Geburten-Regelung. Im Lichte der individuellen und der socialen Hygiene. Von Professor Dr. Med. A. Grotjahn, Privatdozent fur Hygiene an der Universität zu Berlin. Price 6 marks. Berlin: Louis Marcus Verlagsbuchhandlung, 1914.

The diminishing birth rate and the regulation of births in the light of individual and social hygiene is the title of this volume. The subject is one that has been discussed a good deal within recent years. After a brief historical introduction the author presents an analysis of the causes of the diminishing birth rate, attributing this largely to the use of contraceptives. The second section of this work deals with the justification of neomalthusiasm from the individual and social viewpoints. In the third section the dangers of the diminishing birth rate are set forth and the manner in which this diminution has affected various races. The fourth section discusses the outlook with reference to the regulation of the number of births. The statutory and moral aspects are fully dealt with. The author has handled this subject in a masterly manner.

Gelandebehandlung herzkranker Kinder im Mittelgebirge. Klinische und experimentelle Untersuchungen an herzkranken Kindern bei einem Kuraufenthalte im Thüringer Wald. Von Dr. H. Roeder, Spezialarzt für Kinderheilkunde, Städtischer Schularzt in Berlin. Unter Mitarbeit von Dr. C. Bieling leitender Arzt des Waldsanatoriums "Tannenhof"; Dr. W. Spinak Assictenzarzt in Friedrichchroda; E. Wienecker, Städtischer Schulrektor in Berlin. Mit einer Einführung von Dr. Adolf Bickel, Professor an der Universität Berlin, Vorsteher der experimentell-biologischen Abteilung des Königlichen pathologischen Instituts. Mit 1 Tafel, 3 Figuren und Tabellen im Text. Price, $3.60. Berlin: Verlage von August Hirschwald, 1914.

The treatment of children affected with heart disease by sending them into the country for a brief period has been made the subject of an investigation by the authors of this monograph. For this purpose twelve school children affected with heart disease were taken on one of the summer excursions, of which a great number are provided for the poor children of the city of Berlin. They were taken to a moderate mountain elevation in the Thüringian forests and were studied with the aid of the modern methods that are applied to the study of heart disease. Thus orthodiagraphic and electrocardiographic studies were made. Blood pressure, pulse, and changes in the blood and the urine, were carefully studied; and psychological observations were made. These are all set forth in an interesting manner by the author. The results of this treatment, which comprised essentially short walks in the woods was to improve materially the work of the heart and also the general condition of the child.

Black's Medical Dictionary. By John D. Comrie, M.A., B.Sc., M.D., F.R.C.P., Edinburgh; Lecturer on History of Medicine, University of Edinburgh; Lecturer on Clinical Medicine, University of Edinburgh; Assistant Physician, Royal Infirmary, Edinburgh; Assistant Physician, Deaconess Hospital, Edinburgh; Editor "Edinburgh Medical Series." Fifth Edition, completing 30,000, containing 431 illustrations in the text, etc., and 12 plates in color. Price $2.50. New York: The Macmillan Company; London: Adam and Charles Black, 1914.

Black's Medical Dictionary, first published in 1904, has now reached its fifth edition—a sufficient evidence of its popularity. The object of its editor has been to produce a work which, while describing and suggesting treatment for the common domestic ailments, should serve at the same time as a medical dictionary for the laity. The information given is in simple language, and the present volume appears to be thoroughly abreast of the most recent medical theory and practice. The illustrations are good and varied, and the work is a vade mecum of medical knowledge and treatment of considerable value for the lay reader.

Pharmaceutical Botany. By Heber W. Youngken, Ph.G., A.M., Assistant Professor of Botany and Pharmacognosy at the Medico-Chirurgical College; Member of the American Pharmaceutical Association, American Association for the Advancement of Science, etc. Edited by F. E. Stewart, M.D., Ph.G., Professor of Materia Medica, Department of Pharmacy and Chemistry, Medico-Chirurgical College; Author of the "Compend of Pharmacy." Illustrated. Price $1.00. Philadelphia: P. Blakiston's Son & Co., 1914.

This book includes mainly the structural and systematic aspects of pharmaceutical botany. The author has introduced in this volume the important subject matter of his lectures given to the first year students, but has omitted laboratory directions. The work is in two parts. The first part deals with the gross and minute morphology and to a less extent the physiology of the angiosperms. Part two deals with the taxonomy of plants, mainly but not wholly of medicinal value together with the parts used and the names of the official and non-official drugs obtained from these. A bibliography is appended.

Health Through Diet. A Practical Guide to the Uric-Acid Free Diet. Founded on Eighteen Years' Personal Experience. By Kenneth G. Haig, L.R.C.P. (London), M.R.C.S. (England). With the advice and assistance of Alexander Haig, M.A., M.D. (Oxon). Price $1.25 net. Philadelphia: J. B. Lippincott Company, 1914.

Dr. Alexander Haig has long been known as an uncompromising opponent of diet containing uric acid and has propounded his views ably and earnestly, if not always in a convincing manner. His son, the author of the book now being noticed, is as enthusiastic in the same direction, and, moreover, draws from his personal experiences to clinch his arguments. The theory of the Haigs has a good deal to be said in its favor, but is perhaps pushed somewhat too much to the extreme. However, Dr. Kenneth G. Haig's book will well repay perusal, and if he is successful in inculcating the precept "moderation in all things" his work will not have been in vain.

Diseases of the Heart. By John Cowan, D.Sc., M.D., F.R.F.P.S.; Professor of Medicine, Anderson's College, Medical School; Physician Royal Infirmary; Lecturer in Clinical Medicine in the University, Glasgow; Examiner in Medicine, Royal Army Medical College. With chapters on the Electrocardiograph. By W. T. Ritchie, M.D., F.R.C.P.; Physician, Deaconess Hospital; Assistant Physician, Royal Infirmary, Edinburgh, and the Ocular Manifestations in Arteriosclerosis. By Arthur J. Ballantyne, M.D., F.R.F.P.S.; Surgeon, Eye Infirmary, Glasgow. Price $4 net. Philadelphia and New York: Lea & Febiger, 1914.

In no branch of medical knowledge has more progress been made within recent years than in the diseases of the heart and arteries. To Dr. James Mackenzie a great deal of the credit for elucidating the subject of heart and arterial disease is due, while the invention of new instruments of precision, together with the electrocardiograph and the röntgen rays, have rendered it possible for the clinician to solve many problems which without such aid would have been impossible of solution. Dr. Cowan has reviewed the whole subject from the most recent standpoint and from his personal experience has pointed out to the practitioner their bearing upon the practical work of diagnosis, prognosis, and treatment. The result is an extremely useful addition to the literature on heart disease. Dr. Ballantyne writes instructively of the ocular manifestations in arteriosclerosis, and W. T. Ritchie discusses the manner in which the electrocardiograph shows abnormalities of the heart's action. The work throughout is excellently illustrated and may be recommended as an able and lucid description of heart and arterial disease regarded from the latest point of view.

Blood Pressure in Medicine and Surgery. A Guide for Students and Practitioners. By Edward H. Goodman, M.D.; Associate in Medicine in the University of Pennsylvania. Illustrated; price $1.50 Philadelphia and New York: Lea & Febiger, 1914.

The significance of blood pressure is now thoroughly appreciated and the consequence is that literature on the subject is continually increasing in volume. Dr. Goodman has written a handy book, in which he shows how great assistance the study of blood pressure affords in the diagnosis, prognosis, and treatment of disease. The author has a very high opinion of the value of the sphygmomanometer in determining blood pressure and classes this instrument with the clinical thermometer and stethoscope, and points out that its routine employment should be familiar to the physician. The book is a useful addition to the literature dealing with blood pressure.

Die Homosexualität des Mannes und des Weibes. Von Dr. med. Magnus Hirschfeld, Arzt. für nervöse und psychische Leiden in Berlin. Mit einem Namen-, Länder-, Orts-, und Sachregister. Price 12 marks. Berlin: Louis Marcus, Verlagsbuchhandlung, 1914.

The amount of literature on this subject which has appeared in the past twenty years is already enormous. The author of this volume has brought it together and added considerable original matter obtained from an observation and study of many thousands of cases. Indeed, it is sickening to read of the extent of this form of degeneracy in all classes of society, in both sexes, and in all the countries of the world. In every part of the world, the homosexual, as the author states, form a little world by themselves. The United States does not escape, though the number of cases is fewer than in the older countries. The plan of the book is as follows: There are two parts, with thirty-nine chapters. The first part deals with the homosexual man and the homosexual woman from a biological standpoint, and describes their peculiar characteristics. The diagnosis, differential diagnosis, prognosis, and treatment are also fully considered. The second part of the book takes up the sociological aspect of the entire question. Statistics as to the number of cases observed by various writers in the different classes of society in various parts of the world are given. The symbiosis of the homosexual forms an interesting series of chapters. The book is really an excellent encyclopedia of the entire subject. In the chapter on treatment, the methods of Freud are outlined and criticised. On the whole, however, all writers on the subject are treated with broad consideration. The index of writers quoted, at the end of the book, is very extensive. There is also an excellent index of countries and places where homosexuality has been studied, and statistics of more or less value made; also, an index of subject-matter. The book is valuable chiefly to the medical man, and an undesirable addition, perhaps, to a general library.

A History of Laryngology and Rhinology. By Jonathan Wright, M.D., Director of the Department of Laboratories, New York Post-graduate Medical School and Hospital. Second Edition. Revised and Enlarged. Price $4.00. Philadelphia and New York: Lea and Febiger, 1914.

An attempt has been made to link together the story of the records of the nose and throat in medicine with the general drift of medical history. The notes have been taken chiefly from original sources. This work will appeal to the physician for its literary and historical value rather than for its practical usefulness in his every day professional life. It affords pleasure and recreation and much of value for the daily routine. Beginning with Egyptian medicine and continuing down through the other ancient civilizations until the advent of modern procedures, Dr. Wright has given the reader a story full of entertainment and historic interest.

Asthma and Its Radical Treatment. By James Adam, M.A., M.D., F.R.F.P.S., Hamilton Dispensary Aural Surgeon, Glasgow Royal Infirmary. With Four Illustrations. Price $1.50. New York: Paul B. Hoeber, 1913.

The points brought out in this book are founded largely on personal observation. The chief contention is that asthma is due chiefly to a toxemia and in a lesser degree to a nasal and respiratory factor. This conception shifts the treatment from a merely symptomatic one to one placed on a causal basis. The toxemia arises from the bowel and the tissues, due chiefly to an error in nitrogenous metabolism, the result of imperfect oxidation or enzyme action. The poison therefore arises from proteid food or proteid tissue. There is also an associated excess of carbohydrate metabolism. The toxemia shows itself first by catarrh, later by spasms, in the respiratory tract. The conditions allied to asthma are discussed. Many case histories are given.

The Ready Reference Hand-Book of Diseases of the Skin. By George Thomas Jackson, M.D.; Late Professor of Dermatology, College of Physicians and Surgeons, New York; Consulting Dermatologist to the New York Infirmary for Women and Children; Member of the American Dermatological Association and New York Dermatological Society, etc. With 115 illustrations and 6 plates. Seventh Edition, Thoroughly Revised. Price, $3.00 net. Lea and Febiger, New York and Philadelphia, 1914.

It is pointed out in the preface of this book that the growth of dermatology is reflected in the increase in size of this work from its first edition in 1902 and its 502 pages discussing 164 diseases to the present edition with its 726 pages describing 257 diseases. As an example of the accretions to this work may be mentioned the new section on acarodermatitis urticariodes, cutis verticis gyrata, eczema marginatum, eczematoid dermatitis, erythema figuratum perstans, gangosa, granuloma coccidioides, ground itch, hemisporosis, keratodermia gonorrhoica, leucemia cutis, lichenification, lichen nittidus, lichen planus sclerosus et atrophicus, and trypanosomiasis. Like its predecessors this book is eminently practical, containing a large number of illustrations and many prescriptions. Part one consists of sections on the anatomy and physiology of the skin, diagnosis, therapeutic notes, classification, and nomenclature. Part two takes up the diseases of the skin arranged in their alphabetical order. This is an excellent feature for quick references. The appendix contains a list of useful prescriptions.

Society Reports.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Thirty-eighth Annual Meeting, Held in Chicago, May 14, 15 and 16, 1914.

DR. JAMES M. WINFIELD OF BROOKLYN, N. Y., PRESIDENT.

President's Address.—Dr. JAMES MACFARLANE WINFIELD of Brooklyn, N. Y., said that it was no longer necessary to go to Europe to get the necessary clinical experience in dermatology, because the clinical material in America was now equal to that which can be found in any city of the Old World. The impression still held by many that dermatology is but the illegitimate partner of genitourinary surgery was acquired by the fact that formerly the dermatological teaching was conducted by men who made genitourinary diseases a specialty, and diseases of the skin a side issue. A man cannot serve two masters, especially when one is as exacting as the science of dermatology, and either dermatology or genitourinary surgery was enough to absorb all of a man's intellect and ability. The time had come when the leaders of dermatological thought and teaching should make an effort to improve and unify the teaching of skin diseases. Everything possible should be done to correct the custom still prevailing in many medical schools of having syphilis taught by the chair of genitourinary diseases. Granting that syphilis is a constitutional systemic disease, the cutaneous specialist was the one best trained to recognize its varied manifestations. Was it not logical that he would also be better able to teach it than anyone else? We might look still farther beyond and begin to advocate the establishment of a special department and chair of syphilology in all medical schools and hospitals, where the subject could be taught and treated systematically, by men specially trained. To make the study and specialty of dermatology more attractive, dermatologists might boldly enter upon the domains of surgery and rightfully take their own, cutaneous surgery, cosmetic surgery. All would agree that the skin specialist should be able to and does get better cosmetic results than the general surgeon when the operated calling for surgical repair is purely cutaneous. Witness the beautiful and lasting results obtained from the use of the *x*-ray, radium, and dermatological surgery. Dermatology had made great strides along the lines of clinical bacteriological and pathological diagnosis, but in spite of these great achievements our medical brothers claimed that our therapeutic skill was sadly wanting. This criticism was, perhaps, justified. Had dermatologists given the treatment and cure of skin diseases as much attention as they should? Owing to the influx of people from those countries where leprosy was endemic, we were beginning to have an increasing number of lepers in the United States, and the care of these unfortunates should engage the earnest attention of every American dermatologist, and it would seem that this Association should join hands with other medical bodies, in urging upon the United States Government the necessity for a national law and the establishment of a national home or homes for lepers. Dr. Winfield therefore suggested that a committee of this Association be created, to draft a memorial, to be presented to the President of the United States, Senate and House of Representatives, setting forth the dangers of the leper at large, and urging the need of his detention in a place, under national control, where he could receive the proper care, and the scientific investigations could be carried on with a view to the relief of the unfortunate himself, prevention of further spread of the disease, and the eventual eradication of it from the world.

In accordance with these suggestions the Association appointed the following permanent committee: Dr. M. F. Engman, St. Louis; chairman; Dr. Charles J. White, Boston, and Dr. James M. Winfield, Brooklyn, N. Y. The following resolution was adopted: RESOLVED, That it is the sense of the American Dermatological Association, now convened at its thirty-eighth annual meeting, that the care of the leper should be under national control, and that the government of the United States should be respectfully urged to establish a national leper home or homes, where these unjustly persecuted unfortunates could be properly cared for, and where systematic research can be carried on by the distinguished corps of the Marine Hospital Service.

Paronychia: Etiology and Treatment.—Drs. HOWARD MORROW and A. W. LEE of San Francisco, Cal., limited the discussion of this subject to an inflammation of the nail bed and nail fold due to organisms apart from those considered to be the etiological factors in lues, tuberculosis, tinea, blastomycosis, etc. It was the unsatisfactory method of routine treatment of this type of paronychia which stimulated them to a consideration of the subject. Of 16 cases studied, 2 were acute and 14 of long standing, and all had been caused, culturally speaking, but the *Staphylococcus pyogenes albus*. Of these cases 12 were females and 4 males. The former ranged in age from 10 to 60; the latter from 30 to 50. Definite conclusions could not be drawn from such a limited number of cases as to whether age, sex, or occupation bore any relationship to the pathological condition. Thirteen of the cases remained as an uncomplicated paronychia, while three progressed to onychia with exfoliation of the nail. In only one case did the pathological condition involve the feet, and here all of the toes were affected. Of the hand cases all the nails were involved only in two instances, and the remainder varied from one to six diseased nails. The question was raised, Was paronychia primary or secondary? In 14 of the cases studied the condition started about the nails and remained confined to that location until cured. In two cases the disease was secondary to pyogenic dermatitis on other portions of the body. They were unable to determine just what the predisposing cause was in this type of paronychia, but in each case it was possible to obtain from the lesions a pure culture of the *Staphylococcus pyogenes albus*, and, singularly enough, no other organisms grew upon the culture media employed, namely, blood serum and agar. Notwithstanding this experience, it is probable that the *Staphylococcus pyogenes aureus* is responsible for a certain percentage of the cases. For some years treatment by ointments, compresses, powders and in recent years by vaccines had been instituted. A large percentage of the cases treated by these measures have given unsatisfactory results, probably owing to the fact that aside from vaccines these applications do not penetrate into the affected areas. Vaccine therapy did not give them the same satisfactory results as the following prepared of a saturated solution of chrysarobin in chloroform. Chloroform was used because of its high tissue penetrating index; chrysarobin, because of its high staphylococcic bactericidal influence. The plica unguium should be raised from the nail and the affected area swabbed with the preparation. This should be done once daily until there was no longer pus formation. However, it should be remembered that chrysarobin occasionally caused an intense dermatitis, even after one application, and in such cases this treatment should be pursued with caution. All of the authors' patients were cured by this method of treatment in from one to three weeks.

Dr. CHARLES J. WHITE of Boston said that paronychia was not a particularly common infection in the Massachusetts General Hospital, but when it was seen it was very apt to be in the Jewish housewife, and the explanation for this apparently was that they were not allowed to use soap in washing their dishes, for fear that there might be some pig fat in the composition of the soap.

Dr. A. RAVOGLI of Cincinnati had seen a great many cases of eczema of the nail bed, which he would not exactly call paronychia, because there was not suppuration, but only a little oozing, with swelling and formation of a crust around the nail bed. He had found these cases exceedingly stubborn to treatment. The nail had very seldom been affected in the cases seen by him. He had also had some cases of true paronychia, with a great deal of suppuration, and also raising up of the nail, but in these cases incision and removal of the pus gave good results. To correct the eczematous condition referred to, he had found the application of tincture of iodine, going inside the nail bed, in the fold of epidermis, a very good measure.

Dr. D. W. MONTGOMERY of San Francisco thought a great number of these cases were due to the streptococcus.

Dr. GEORGE H. FOX of New York City referred to the relation of the manicurist to the etiology of paronychia. Recently the newspapers in New York City had had a number of special articles on the question

of forcing manicurists to obtain licenses on account of the bad results from their work.

Dr. Morrow, in closing, said that applications of tincture of iodine were very efficacious, as referred to by Dr. Ravogli, and also those of nitrate of silver.

Epithelioma of the Hand Following Traumatism Resembling a Granuloma.—Dr. Howard Fox of New York City said that his interest in the subject of cancer of the extremities, and of the hand in particular, was aroused by the opportunity to observe a case which presented a number of unusual features. The patient was a man of 48, whose previous history showed only an attack of measles when a child, and an attack of "blood poisoning" in the left wrist, for which incision was made, and which healed at the end of sixteen weeks. Syphilis denied. During the summer of 1911 he was bitten on the back of the right hand by a horse, which injury caused an open wound at the junction of the fifth metacarpal bone, which healed in the course of two weeks. Five or six weeks later an open sore again appeared on the back of the right hand, which gradually extended in area and became red and swollen, discharging and crusted. When first seen by me the skin of the right hand showed the characteristic symptoms of ordinary senile skin. The entire dorsal surface was swollen, edematous, and tender, the swelling extending to the wrist and first phalanges. On this area were serpiginous, rather sharply bordered ulcerating and crusted lesions, extending from the knuckles to the proximal ends of the metacarpal bones. The central portion was covered with epidermis, but was swollen, boggy and tender. By pressing on almost any portion of the back of the hand a considerable amount of thick yellowish pus could be expressed. The clinical picture was that of a granuloma due to tuberculosis, blastomycosis, actinomycosis, or possibly syphilis, complicated by an extensive suppurating cellulitis. Wassermann reaction was negative. A biopsy was then made, which showed the presence of a most typical squamous-celled epithelioma. Patient refused operation, and six *x*-ray exposures were given. He was also treated by wet dressings of permanganate of potash. Examination of the chest showed some coarse râles, slight dullness and diminished breathing. A radiogram of the chest was made, which indicated an extensive involvement from the level of the fifth dorsal down to the lower border of the ninth, the irregularity of the shadow indicating carcinoma. The patient lost weight and became cachectic. Dysphagia steadily increased, and after gastroenterostomy for its relief the patient died. Epithelioma of the hand was a comparatively rare condition, and in the vast majority of the cases occurred upon the dorsal surface. In spite of being histologically, as a rule, a malignant type of cancer, it ran a slow and relatively benign course, seldom invading the lymphatic glands. The majority of cases developed upon a basis of chronic inflammatory tissue; very few arose after a single tranmatism.

Dr. Alfred Schalek of Omaha had had a case very much like the one reported, but in his case the growth occupied the whole dorsum of the hand. He suspected malignant disease at first. He did not think of epithelioma for the reason that he had never seen a case of epithelioma in the hand. The case was very interesting on account of the extreme pain. The growth was excised, and later a skin graft used, which was followed by recurrence. The patient was referred to a surgeon, who amputated the arm, and after that nothing more was heard from him, but in this case the process certainly was not very benign, and looked to the speaker to be very malignant.

Dr. W. A. Pusey of Chicago had seen a considerable number of epitheliomas of the hand, on the back of the hand. His experience in general corresponded with Dr. Fox's, that epitheliomas on the back of the hand were relatively not very dangerous, but this had set him to thinking of one thing during the last few years, namely, why epitheliomas on the back of the hand occurring in *x*-ray skins were so excessively dangerous. He thought it was a general fact that those cases of epitheliomas in *x*-ray hands were very liable to metastasis, and he would like to know what was the possible reason for these lesions being dangerous, while the ordinary ones were not so. He had seen only one epithelioma on the palm, and that was an exceedingly interesting case.

Dr. M. B. Hartzell of Philadelphia spoke just a word about the sequence of epithelioma and acute traumatism. He had seen three or four patients in whom epithelioma had followed immediately upon a slight injury. One of these occurred upon the end of the nose of a woman between fifty and sixty years of age, following a scratch, which never healed, and was followed within a few weeks by a typical epithelioma. In another case the epithelioma occurred on the inner surface of the lip, following a traumatism inflicted by a dentist. He could also recall two cases of carbuncles on the back of the neck, which were followed immediately by epitheliomas; that is, the wound left by the carbuncle never healed, and epithelioma developed on that site. Perhaps his experience had been unusual.

Dr. Martin F. Engman of St. Louis said the case of Dr. Fox was extremely interesting on account of the epithelioma occurring so quickly after the trauma. It seemed to illustrate the theory of Ribbert uniquely, in which the normal epithelium through an ulcerating surface was misplaced and separated from its kindred, and thus underwent a typical physiological functionating, and rather quickly developed into an epithelioma. Quite a number of cases of epitheliomas of the back of the hand were seen, but they usually originated from a keratosis. He had seen several cases of epithelioma of the hand following *x*-rays, and one case, he thought, was fatal. This seemed to be due to the poor regenerative qualities of the connective tissue, possibly, and the poor condition of the vessels. In a large proportion of these cases the epithelioma was preceded by secondary degeneration of the connective tissue, as found by White upon investigation.

Dr. G. W. Wende of Buffalo had had a case of epithelioma on the palmar surface of the hand, following an injury. It developed soon after the traumatism, and grew very rapidly. The course, from beginning to end, was less than a year and a half in length.

Dr. Udo J. Wile of Ann Arbor, Mich., thought attention might be drawn to the one notable exception, at least to the relatively benign nature of epithelioma of the extremities, in that following the ingestion of arsenic preparations. A number of cases had been reported. A few years ago, in looking up the literature, he was struck by the large number of arsenical growths, all of which were fatal.

Dr. Sigmund Pollitzer of New York City thought the class of cases the subject of Dr. Fox's paper might well be brought under that group of epitheliomas which were the result of misplacement of the epithelial cells, caused by the trauma. In this respect this class of cases did not differ materially from another class of epitheliomas that occurred commonly as the result of a nevus, with cellular proliferation. He wanted to say a word about a practice which was quite common among dermatologists of treating nevi which depend upon cellular inclusions, as moles and pigmented moles, by cauterization by one method or another. He had seen several cases of nevi that had been treated in that way, and he thought it was a bad practice. A cellular included nevus should be treated like an epithelioma, or let alone. He wanted to lay particular emphasis upon that point. Ninety-nine times out of a hundred nothing happened, but in the last case, if a few cells were left behind, they were subjected to terrific irritation from the treatment, and were very apt to degenerate into a malignant process.

Dr. Henry H. Hazen of Washington, D. C., had had the opportunity of going over one thousand cases of epithelioma of the skin with Dr. Bloodgood, at Johns Hopkins Hospital. In that series forty or fifty originated in the limbs. In from two to ten years absolutely every case of prickle-celled epithelioma in which the glands were not taken out developed metastases. One or two developed metastases as late as ten years after. These cases were all proved malignant by microscopical examination. When we have a prickle-celled epithelioma, we should always excise the draining glands, in addition to taking out the epithelioma itself. In addition, we ought to be very careful about our method of doing biopsies on prickle-celled tissues. We left both the lymphatics and blood vessels open, and there was a very good chance for any cancer cells to escape into those cells. We should use a dull knife, and if we could not do that the wound should be immediately cauterized as soon as the tissue was removed.

Dr. W. T. Coriett of Cleveland said his experience might have been unique, but next to the epithelioma of the face, he had encountered epithelioma of the back of the hand most frequently, and in these cases of epithelioma of the back of the hand he had been impressed with the frequency with which metastases had occurred. He had attributed that to the fact that

epithelioma on the face was usually a conspicuous lesion and relief was sought at an early time, whereas an epithelioma occurring on the hand was usually less conspicuous, and therefore was liable to be neglected.

Dr. W. A. PUSEY of Chicago questioned the accuracy of any statistics that said that every case of epithelioma of the back of the hand had metastases. He thought he could produce cases from his experience that would prove that it was certainly extraordinary and not usual. He also challenged the statement of the physician who said that every epithelioma of the back of the hand should be followed by extirpation of the lymphatics. He did not think it was common sense, good or necessary surgery.

Dr. HAZEN said that he had found prickle-celled epitheliomas, and about 80 per cent. were of this kind.

Dr. FOX, in closing, said Dr. Engman had referred to the short time between the traumatism and the development of the epithelioma. He did not think six months was such a very short time. However, he just mentioned the traumatism as a suggestion; he thought it would be impossible to prove that that traumatism with the resulting scar was the actual cause of the epithelioma. In one of the cases reported in the discussion the epithelioma appeared in the scar resulting from the bite of an animal ten years afterwards. From what he had been able to read in the literature, he had found that epithelioma occurred on the sole of the foot a good deal more often than on the palm of the hand, and he thought some of these cases had started in perforating ulcers. Certainly, the majority of cases of epithelioma of the extremities arose on a basis of some chronic inflammatory process, a lupus or a fistula, in connection with an osteomyelitis or a chronic dermatitis or a chronic ulcer of some sort, and a relatively small number arose on apparently normal skin. In regard to the malignancy of the cases occurring after *x*-ray work, according to the statistics of Brunn and Volkmann the most malignant type of epithelioma was that which developed upon weals and moles, congenital or those which appear later in life.

Purpura Annularis Telangiectodes.—Dr. GEORGE M. MACKEE of New York City said this affection attacked young male adults, although two cases had been noted in infants. The eruption was always situated on the anterior and lateral surfaces of the lower limbs, below the knees, with occasional lesions above the knees and on the arms, and very rarely on other portions of the body. The appearance of the eruption was nearly always preceded by rheumatic pains. Otherwise there were no subjective symptoms. The disease was divided into three fairly well defined stages: First, telangiectatic; second, purpuric and pigmentary, and, third, atrophic. Regarding the differential diagnosis and etiology, many cases gave a positive tuberculin reaction, but at the same time many did not. Inoculation experiments had been negative. These facts, together with the clinical and histological pictures, would seemingly rule out the possibility of tuberculosis. Occasionally, in syphilis, an annular purpuric rash was present, which was due either to the syphilis or possibly to the mercury. This eruption was usually limited to one small area, was evanescent in character and disappeared without atrophy and with temporary pigmentation. The etiology of the disease was unknown, but was thought to be either a neurosis or a reaction to some toxic substance. It could be differentiated from any known dermatosis, and was undoubtedly an entity.

Dr. A. SCHALEK of Omaha said whatever this skin disease might be, he certainly did not think that the name purpura was a good one. It did not agree with any of the characteristics of purpura as he knew them.

Dr. A. RAVOGLI of Cincinnati said it was a beautiful thing to place new names, and to try to designate diseases of rare quality by these new names, but we should remember that we had acne necrotica and tuberculides, but whether they had just the same pustule formation, with resulting scar, as that described by Dr. MacKee, he did not know.

Dr. W. H. MOOK of St. Louis had seen four or five of these cases in the last seven years, and placed them under the classification of atrophic dermatosis of unknown origin. One of the cases had quite an ulceration, about the size of a dime, that had existed for something like two years, and under all sorts of treatment had refused to heal.

Dr. MARTIN F. ENGMAN of St. Louis said his attention was first called to this condition several years ago by Dr. Mook, and since then he had seen several cases, and had called them "Mook's disease." Then, in looking over the literature about six months ago, he came across some articles about this disease. Most of these cases reported in the literature occurred in railroad men, and those who were on their feet a great deal.

The Abderhalden Technique as Applied to the Diagnosis of Syphilis.—Dr. H. R. VARNEY of Detroit, Mich., said that Vaughan's work and suggestions on the parenteral injection of proteins gave the new trend to our conceptions of immunity. As we were becoming more and more aware, immunity was a simple matter of parenteral digestion by ferments elaborated by the body cells. These ferments might be retained within the cells or discharged into the blood, or might be shown in both the blood current and certain groups of cells coincidentally. Abderhalden had applied the principle of parenteral digestion *in vitro* by subjecting the foreign protein to the ferment present in the blood serum, showing that the protein was broken down into simpler dialyzable bodies which might be detected in a dialysate by determining their aminoacid groups with triketohydrinhydrenate. The technique consisted in mixing the immune blood with the thoroughly coagulated, washed, antigenic protein in a dialyzing thimble and hanging the thimble in a capsule of distilled water. The capsule was incubated for twelve hours or longer, and finally the dialysate was tested for aminoacid groups with ninhydrin. The possibilities of Abderhalden's work were numerous, having been applied already to many conditions from psychiatry to infectious diseases and to derangements of the internal secretory apparatus. Theoretically the enzyme test as applied to syphilis had great advantages. In the first place it should be specific; second, the technical procedure was simple in principle and the materials required small in number and amount. The technique consisted in syphilitic tissue plus suspected blood in a dialyzing thimble, incubation, and subsequent testing for aminoacids by the biuret reaction or ninhydrin. However, in applying this test we were confronted with certain technical difficulties. First, the blood must be drawn in such a way that no hemolysis would take place. The technique of withdrawal and subsequent handling must be reasonably aseptic, since bacterial decomposition split proteins of all sorts and gave us amino groups in our dialysate. The quantity of blood sshould be sufficient to obtain three or four c.c. of serum. The serum must be reasonably fresh inasmuch as the ferment disappeared probably inside of twelve hours. Because of the difficulty in maintaining an absolutely aseptic condition of the ingredients it was necessary to use toluol to prevent bacterial growth. Of seventy-five cases examined experimentally the following conclusions were drawn: (1) That the specificity of the Abderhalden technique applies to syphilis. (2) That syphilitics have in their blood serum enzymes which react with the protein of the organism. (3) That tissue derived from active human lesions is more specific than syphilitic tissue of the rabbit. (4) That mixed infection in the human lesion gives rise to error in mixed infections, as shown in our cases of sinus disease, furunculosis, and so forth. (5) That further work will be required to determine whether all syphilitics have the power of developing ferment, and at what stages of the disease the test is present or absent. (6) We believe that polyvalent antigens prepared from several stains of pure culture of the spirochete offer the best hope for further success with this technique. (7) That the degree of success with the test varies in proportion to the care and precision exercised in its execution.

A Study of the Spinal Fluid with Reference to Involvement of the Nervous System in Secondary Syphilis.—Dr. UDO J. WILE and Dr. JOHN HINCHMAN STOKES, Ann Arbor, Mich., said: The view that the central nervous system was attacked late in the incidence of syphilis, and that the various forms of cerebrospinal syphilis were manifestations of the tertiary nature of the disease was no longer tenable. That there existed in the nervous system a peculiar tendency to latency and to slow, insidious development of the disease process was undeniably a fact. The fate of every syphilitic, however, with regard to the incidence of cerebrospinal lues, whether this occurred early or late in the course of the disease, was in all probability determined in the first months of the infection. The infection of nerve tissue by the spirocheta pallida was undoubtedly dependent upon several factors, namely, individual susceptibility, neuropathic heredity, alcoholism and trauma. Also the strain of the organism, hypothetically

at least, might also be a determining factor in the localization of the disease process to the nervous system. The explanation of the selective action of this organism upon certain systems would in time be discovered through the unraveling of its life history and its separation into definite strains. Ravaut, Widal, and Sicard, even before the Wassermann reaction was applied to their findings, described marked chemical and cellular changes in the cerebrospinal fluid of syphilitics, both early and late. Ravaut believed the nervous system to be affected in from 60 to 70 per cent. of all cases during the secondary stage. Engman, Gorham, Buhman, and Davis, in 1913, concluded that the nervous system was attacked during the first two years of infection in less than 10 per cent. of the cases. In none of their cases in which there was an early involvement were any active cutaneous symptoms present. There seemed to the authors no reason why one should not expect to find the nervous system involved or at least invaded by the spirocheta early in the course of the disease. If we recognized that early in the disease dissemination of the syphilitic infection was hematogenous it was hard to see just how the nervous system could escape. We must remember that a negative finding at a particular time must be carefully scrutinized from two standpoints: (1) That the involvement was not yet present; (2) that it might not be sufficiently extensive to cause a meningeal reaction which would be manifested by a practical test. The report was based on a study consisting of a total of thirty-six cases representing all types of secondary syphilitic manifestations, including several late recurrences and precocious malignant forms of the disease. In all the cases a positive objective diagnosis could be made from the lesions, and the Wassermann reaction on the blood was employed only for confirmation and comparison with the spinal fluid findings. The reaction in the blood was strongly positive in thirty-four cases, no record having been preserved of the other two. In each spinal puncture about 5 c.c. of fluid were drawn and this divided into three parts, the first being used for the cell count, the second for the Wassermann reaction, and the third for the determination of the albumin and globulin content. In the course of the investigations it became evident that a study of the cranial nerves might contribute facts of importance relative to the extent and character of central nervous involvement, and accordingly routine examinations of the fundus of the eye were made in twenty-six out of thirty-six cases. To this examination they felt that special importance might be attached, since the anatomical relations and character of the optic nerve and the retina, as portions of the central rather than the peripheral nervous system, made ophthalmoscopic study of these structures a near approach to objective examination of the brain itself. Of the thirty-six cases examined twenty-four showed involvement of the central nervous system as gauged by the cerebrospinal fluid findings. This represented 66.6 per cent. of the total. It was shown that of efficiently treated cases only 25 per cent. showed cerebrospinal involvement, while of inefficiently treated and untreated cases 70.8 per cent. showed such involvement. However, it was well to bear in mind the possibility that the well treated cases might have shown an evanescent reaction earlier in the course of the disease. But in spite of this the figures seemed at least suggestive. Regarding general health and cerebrospinal involvement, classifying severe and moderate disturbances together, and slight and none together, the proportion of involvements in severe disturbances was as three to one, while in mild disturbances it was roughly as two to one. It was apparent in the series that there was an appreciably higher proportion of involvement of the nervous system in patients presenting severe constitutional symptoms than in those presenting mild symptoms.

Conclusions.—1. A large proportion of all patients in the secondary period of syphilis, in the series 63 per cent., showed evidences in the spinal fluid of the involvement of the central nervous system. 2. From the special examinations made we must conclude that this does not represent the whole number who will at some time show or who have not already shown a reaction on the part of the central nervous system. 3. The absence of findings indicative of meningeal reaction in a single examination cannot be taken as conclusive evidence of freedom from central nervous involvement. 4. Any of the findings, lymphocytosis, increased albumin and globulin content and positive complement fixation test may be present alone or in varying combinations, and each indicates involvement of the central nervous system. 5. Comparing this high ratio of early involvement with the relatively low ratio of later involvement as compared with the total number of syphilitics we must conclude that the early involvement is for the most part a transitory manifestation. 6. The central nervous system is particularly likely to show involvement in cases in which the eruption is papular or follicular in type. 7. Marked subjective symptoms, such as headache, insomnia, and nervous irritability, were for the most part accompanied by positive findings in the fluid in our series. 8. In a general way, cases in which there had been little or no treatment showed a higher percentage of involvement than those in which vigorous treatment had been inaugurated. 9. Involvement of the central nervous system was found in a relatively high percentage of those cases in which the general health was considerably affected. 10. The commonest findings indicative of meningeal reaction was the increased globulin and albumin content, the positive Wassermann ranking next, and lymphocytosis last. 11. As an aid to diagnosis and as a possible guide to prognosis, the value of the spinal puncture in cases of secondary syphilis can scarcely be overestimated.

Dr. J. A. Fordyce, of New York City, had for a long time been convinced that there were various strains of the spirochetes and that there was a strain that had a special predilection for the nervous system. Dr. Nichols, of the Army Medical School of Washington, had recently published a very suggestive article on a strain of spirochete that had a given infective power. Regarding the percentage of cases of syphilis showing involvement of the nervous system the majority of neurologists claimed that there were not more than from 5 to 10 per cent. of syphilitics who showed such involvement. If a larger percentage than that showed involvement in the early stage of the disease it must, as Dr. Wile had said, be a passing infection, a hyperemia of the meninges, which passed on. He had been making a study of the spinal fluid in late syphilis, in tabes, paresis, and various forms of cerebrospinal syphilis for the past two years, but only in the last three or four months had taken up the question of the frequency of involvement of the nervous system in secondary syphilis. He had examined the spinal fluid in about thirty cases in various stages of the secondary period of the disease during the last three months, both for the globulin content and lymphocytosis, as well as the Wassermann reaction. He started out firmly convinced that he would find from 40 to 50 per cent. of involvement of the nervous system, but to his surprise he had found it considerably smaller than that. Repeated punctures should be made in the same case, as the fluid might be negative this week and positive a month later. We should make the examination in the later period of the secondary stage, and especially after treatment with salvarsan. One, two, or three injections of salvarsan were apt to develop a latent reaction in the fluid, and you are more apt to get changes after the patient had been under treatment for some time.

Dr. J. F. Schamberg of Philadelphia said we were coming to recognize that syphilis was not a cutaneous or a nervous disease, but a constitutional disease, in which every tissue and organ might at some period be involved, and Dr. Wile's studies showed us with what frequency the nervous system was involved, often at a very early stage of the infection. It was necessary not only to study the blood in these cases, but also the cerebrospinal fluid in order to prevent later disastrous results affecting the nervous system.

Dr. Sigmund Pollitzer of New York thought we were just on the threshold of our knowledge of this subject of the involvement of the central nervous system in syphilis. When we reflected for a moment on the pathological process of syphilis, the mode of infection, and the spread of the organism it seemed likely to him that not 15, 25 or 68 per cent. of the cases would show early in their course involvement of the central nervous system, but probably, when we know more about the disease, we would find that 100 per cent. of the cases showed such involvement at some stage early in the disease. The spirochetæ got into the blood and were carried everywhere, which, of course, included the central nervous system. That we did not get manifestations of syphilis in every tissue of the body must be due to the fact that the spirochetæ were destroyed by the natural forces of defence of the organism. This, of course, was purely theoretical, but was based on what

we know of pathogenic organisms in general. The practical lesson that we should draw from these studies and those that will follow was the necessity of early and most energetic treatment. Specialists should impress this fact on the general practitioner, who saw 100 of these cases to one that the specialist saw, and in whose hands the future course of syphilis depended. It was a grave responsibility that rested on specialists in the matter of proper teaching of the subject of syphilis.

Dr. WILE, in closing, said that Dr. Pollitzer had said exactly what he would have liked to have said, namely, that probably not 68 per cent. of all cases showed involvement of the central nervous system, but probably 100 per cent. At least in 100 per cent. of the cases there must be an infection of the central nervous system. The difference between Dr. Fordyce's statistics and the speaker's might be accounted for by the fact that all the cases examined in his series had active manifestations present.

Dr. FORDYCE said that most of his cases had active lesions.

Dr. WILE thought, as mentioned by Dr. Fordyce, that most of the nervous conditions were transitory phenomena, and for the most part energetic treatment directed to the general syphilis served to clear up the syphilis of the central nervous system. Just how many of these cases in which the cerebrospinal system was involved early became the late cases of tabes and paresis it was impossible to say, or as to whether they fell into this group or not. It was highly probable that of this number 5 per cent. were drawn from these cases of early involvement.

The Use of Calcium Lactate in the Treatment of Certain Dermatoses.—Dr. CHARLES J. WHITE of Boston said that about the time Sir Almroth Wright first wrote about the opsonic treatment of disease, one of his pupils, Dr. Ross of Toronto gave a talk to the staff of the Massachusetts General Hospital on the use which Wright was making of calcium salts in the treatment of urticaria, purpura, and sick headache. Ross gave the following prescription: Tr. capsic., m. viii; calcium lactat., gr. clx; aq. chloroform, Oi; two tablespoonfuls in water before meals. Since that time—about seven years ago—the author has tried this remedy in many and various skin diseases in a more or less desultory way, but about a year and a half ago, believing that calcium had shown decided curative powers in certain instances, he decided to make a thorough therapeutic trial of the drug. His belief in at least the theory of the method had been strengthened by several articles which had appeared from time to time in the medical press. He had prescribed calcium in many different conditions, but by elimination of the unsatisfactory tests the final trials had been limited to the following diseases and conditions: Hyperidrosis, pernio, herpes simplex, erythema multiforme, urticaria, livedo, purpura, and angioneurotic edema. In addition to the calcium salts, patients had been asked to partake as freely as possible of food rich in calcium, and had been urged to avoid raw fruits and all acid foods, for it had seemed to him that many people suffering from the suspected diseases had been large consumers of these articles of diet. External treatment had been prescribed in all cases, a factor which vitiated the scientific value of the whole work, but it must be borne in mind that most of these patients were referred to the writer by general practitioners who had been unsuccessful in the previous treatment of these individuals, and, furthermore, that these men and women were mostly wage-earners who deserved as speedy restoration to health as was possible. Also the work was necessarily hampered by the fact that all these patients were ambulants, who obeyed or broke laws as the spirit moved them. The cases of urticaria had done well; statistics showed twelve with great improvement; two some improvement, and nine others, not reported, none whatever. Cold figures were not always our only means of judgment in medicine, but from personal contact with these patients it had seemed that the ingestion of calcium had been followed by improvement in the majority. In the cases of erythemia multiforme, seven of the group showed decided improvement and six exhibited what one might call the normal, although perhaps quickened, evolution of the disease following the ingestion of the calcium. The pernio group showed that six patients were practically cured in a short space of time; three were decidedly benefited, while three only were not helped at all. This seems a good showing, considering the frequent intractability of the disease. In hyperidrosis cases four patients to all intents and purposes were cured, and one decidedly benefited—which seemed very satisfactory considering the frequent obstinacy of the condition, and in this particular group several of the patients had suffered for a number of years very severely. The cases of purpura rheumatica, livedo, sick headache, and erythema toxicum were too small in number to be of any scientific value, and yet the degree of success attending their treatment was striking and worthy of remembrance in the future. In summing up his experiments Dr. White thought it seemed fair to state that calcium was certainly not a specific for any of the diseases in any sense of the word, but it was a drug which might render distinct and most welcome service in any one of them, and a drug which should always be tried in obstinate examples of the conditions above cited.

Dr. W. A. PUSEY of Chicago was very much interested in Dr. White's work. He had used calcium salts in intractable cases of urticaria, erythema multiforme and intractable eczema, but had to confess to having had practically no evidence of its value. He had first used calcium chloride and later calcium lactate, but had not been able to convince himself of its value to any extent whatever. However, if Dr. White, who was such a careful observer, had found calcium lactate useful in such an intractable a condition as hyperidrosis, he was going to try it again.

Dr. M. B. HARTZELL of Philadelphia had tried calcium salts very extensively, and had not yet seen a single instance in which he thought the patient had been benefited in the remotest degree. Still, he would try it again.

Dr. D. W. MONTGOMERY of San Francisco had given calcium lactate in a very interesting case of erythema multiforme, which was proven to be due to the *Bacillus coli communis*, and got no appreciable amelioration of the symptoms.

Dr. DAVID KING-SMITH of Toronto said that calcium lactate had been tried in various conditions in the hospital with which he was connected, and he thought its use had been rather disappointing.

Dr. WHITE, in closing, said he had tried to make his paper as conservative as possible. He had also met with a good many failures in the use of this drug. He did not think the giving of the calcium lactate was the whole thing. Acids and foods that contained calcium should be eliminated, and, above all, the use of magnesium at the same time should be stopped. The two drugs are opposed in their results; they neutralize each other, and no effect is obtained. There were perhaps as many failures as successes, but he thought it was a drug which should be held in mind when treating these very obstinate and distressing conditions of the skin.

External Vaccine Therapy.—Dr. HARVEY P. TOWLE of Boston said the results of the tentative experiments with external vaccine therapy were so encouraging in the Massachusetts General Hospital in 1912 that the method had been used with constantly increasing frequency. His paper was based on the personal observation of more than 150 private cases where vaccine was used externally. These cases might be roughly divided into three groups: (1) Those in which the results bore most on the question of practicability; (2) upon the form of the vehicle and mode of administration; (3) upon the therapeutic indications, the dosage and effects. No fixed formula had been followed, both composition and proportion having been varied as the varying conditions of the case seemed to indicate. The indications were that external vaccine therapy was most efficient in the treatment of the acute inflammation of infectious disease, whose seat was superficial and therefore easily reached from without. Of all infectious processes, the staphylococcic was the most easily influenced by external vaccine therapy, and in this the resemblance to the internal method was exact. Vaccine injections were never more efficient than in the treatment of furunculosis, but had also been used successfully in cases of acne, sycosis, and with seeming success in psoriasis, and also in oily seborrhea of the scalp. The results on the superficially seated lesions of impetigo contagiosa were usually excellent. Tuberculin was also used externally in several cases of lupus vulgaris, with good effect.

Dr. JOSEPH GRINDON of St. Louis about three weeks ago was called to see a case of lupus which had existed for twenty-five years. Various treatments had failed to give more than fair temporary improvement. It occurred to him that if it was true that the antibodies were put out very largely in the immediate environs of the invading organism, that that would be a good

place to which to apply the vaccine. Of course, one might say that just at that point the invading organism was already at work, and that it did not seem rational to put in more of the dead bodies of that organism. But thinking, again, how very few bacilli there were in lupus, he thought that perhaps an additional rubbing in of the organism might produce a large output of the antibodies. So he took the Moro ointment, just undiluted, and twice a week rubbed it in for five minutes at a time. There was quite a decided improvement, which continued for several weeks. After a month, however, the lesions flared up again, and he then lost track of the patient.

Dr. Joseph Zeisler of Chicago said many cases of impetigo contagiosa had cleared up under his observation with simple treatment in five days. He remembered a case of lupus erythematosus in which he performed scarification, and applied a little carbolic acid, and in a week the patient was cured. There were so many different factors entering into the cure of our cases that it was very difficult to draw any conclusions at all. The mechanical element of rubbing grease into a scaly eruption might help some. He admired Dr. Towle's enthusiasm, and did not wish to criticise him.

Dr. Towle, in closing, speaking of lupus vulgaris, said he had come to the conclusion that the reason this treatment did not work in the indurated forms so well as in some of the others was an anatomical one, due to the disease process itself. Many of these cases were soft on top. Just how much this method was worthy of further investigation, he would not attempt to say. He drew no conclusions.

A Case of Generalized Congenital Keratodermia.—Dr. Frederick S. Burns of Boston reported a case in which the patient was sixteen years of age. The dermatosis was generalized, showing special preference for the flexures of the hands, knees and feet, and the face. The type of lesion was that of an abnormal cornification varying from spine-like elements to marked keratotic thickening. Exfoliation was slight. The process extended on to the lips, buccal and nasal mucous membrane, presenting on these surfaces a rather dry superficial thickening that closely resembled leukoplakia. The corneæ were thickened and uneven, and surrounded by enlarged blood vessels, which also infiltrated the cornea. The intrinsic tissues of the eyes were unaffected. Deafness was total. The Wassermann was negative. The mucous membrane lesions were unusual, and those of the eyes and ears extremely rare.

Dr. Joseph Grindon of St. Louis was very glad Dr. Burns had once more called attention to the distinction between hyperkeratosis congenita and ichthyosis. So far as he was acquainted with the conditions, there was no such thing as congenital ichthyosis; that is, it was never present at birth, although developing in the first and second years of life.

Dr. D. W. Montgomery of San Francisco asked the essayist if the usual clinical picture did not show that the palms of the hands were old and smooth?

Dr. S. Pollitzer of New York asked Dr. Burns to differentiate this process from the possibility of an atypical acanthosis.

Dr. A. Ravogli of Cincinnati said it was difficult for him to understand the difference in these cases between pityriasis rubra pilaris and ichthyosis. In the latter condition the affection was present on the surface of the epidermis, but the effect did not go into the follicles. In the case of Dr. Burns, according to the pictures exhibited, the openings of the hair follicles were all studied with epidermis, and the speaker had always found this condition in pityriasis rubra pilaris. In ichthyosis the palms, soles and nails were very seldom affected in the way described by Dr. Burns in his case, and this also suggested pityriasis rubra pilaris to Dr. Ravogli.

Dr. Burns in closing, in answer to Dr. Montgomery's question as to the involvement of the palms and soles, said that the process, as seen at the time when the photographs were taken, did not show the aggravated condition present a year ago. At that time it presented the appearance of pityriasis rubra pilaris or keratosis follicularis. It had been his impression from reading textbooks and various papers, and looking over the literature, that there had seemed to be a consensus of opinion, although an artificial one, that the palms, soles, face and scalp were not usually affected in ichthyosis vulgaris. He did not emphasize that point, because he realized that it was a clinical and artificial distinction. However, the existence of a greater degree of inflammatory infiltration in the papillary layer of the skin in cases of ichthyosis vulgaris was very common. In his case such changes were entirely absent. There was, however, a slight hypervascularity, which might help to explain the underlying erythemia, and that might be a part of the acanthosis hyperkeratosis having to do with the deformity of the skin. Regarding Dr. Pollitzer's question, with reference to acanthosis, the clinical symptoms presented no pigmentation. He wished to lay special emphasis on the unusual involvement of the mucous membranes and the organs of special sense, because there seemed little doubt, after consultation with the various specialists who concerned themselves with the examination of the eyes and ears, that the condition of the skin was contiguous with any part of the process having to do with the epidermatosis.

An Instance of Asymmetrical Raynaud's Disease.—Dr. Douglas W. Montgomery of San Francisco reported the case of a woman, 47 years of age, who came to the speaker with a swelling of the fingers of the left hand, and because of severe pain which did not yield to ordinary treatment. Motion increased the pain. The fingers of the left hand were swollen and stiff; the skin over them was stretched, obliterating the joint folds, and presenting a smooth, glistening, red surface. The volar surfaces of the terminal phalanges, including the tips, were grayish-white, and looked as if blistered. The thumb was the least affected. The nail beds were cyanosed. The hand was swollen and red, with a tint of blue. There was no mottling of the arm, nor of the general cutaneous surface. Besides intense pain, there was also burning and itching in the fingers, and the whole arm ached. The terminal phalanges, excepting that of the thumb, were analgesic to superficial pin-prick. Deep pin-prick caused pain similar to that roduced by pressure. The terminal phalanx of the thumb was hypersensitive to needle prick. Blood pressure was 10 millimeters of mercury less on the affected left upper extremity than on the right. Four years previously the patient had been operated on for gallstones, and four months after the operation the left thumb became a dead white, followed by redness, coldness of the hand and swelling of all of the other fingers, with tingling sensations around the base of the nails and itching of the tips. A year ago she had a similar attack, and off and on since then has had like disturbances, but not so severe as the last attack. Her general condition was not good. She was gastroptotic; had dizzy spells; was pale and the left radial artery felt uneven to the finger, and more rigid than the right. There was a blowing systolic murmur, best heard in the aortic area. The Wassermann was negative. She had not taken ergot, nor had she used any bandage on the arm, hand or fingers. She had not used carbolic acid. No cervical rib was present. Cold was not an etiological factor. Alcoholism, asthma, rheumatism, were all excluded as possible causes. Within a week the little finger became blue-black, and a few days later the tip of the middle finger also became blue-black. The other finger-tips had approached more nearly a normal color. The two gangrenous finger-tips were not shed. The other fingers became practically normal. About six months afterwards, during a cold spell, the index and ring fingers became blue; the thumb remained normal; the two gangrenous finger-tips were unaffected.

Report of a Case of Colloid Degeneration of the Skin.—Dr. Milton B. Hartzell of Philadelphia was convinced, from a study of one typical case occurring in a man, 43 years of age, that colloid degeneration of the skin of the type represented by the so-called colloid milium was not a disease of the elastic tissue alone, but affected the collagen and elastin in equal degree. The cells of the epidermis might share in the degeneration, although this was probably infrequent.

Dr. G. F. Fox of New York City referring to the cases which he reported many years ago as colloid milium, was convinced at that time that they were not true cases of colloid degeneration, but similar to a number of cases that had been described. In his cases the tumors looked firm, but were soft, and when dug out of the skin were found to be cystic and removal was followed by an extreme amount of hemorrhage. There was scarcely any cicatrix left after healing.

Dr. Charles J. White of Boston said the case reported some years ago by him was very different clinically, in that it had very few lesions, and decidedly larger ones. Histologically, Dr. Hartzell's patient and his were extraordinarily identical. His case, however, was much farther advanced.

Dr. HARTZELL, in closing, said it seemed to him to be folly to give different names to this one condition. Why not call it degenerative elastin?

Urticaria Pigmentosa: Particularly in Regard to Its Pathology.—Dr. FRANK CROZER KNOWLES of Philadelphia had seen five cases of this disease. It should be disassociated from urticaria, as the course, symptoms and the histologic mast cell picture were entirely distinctive. A congenital abnormality of the skin had apparently been proven in urticaria pigmentosa by finding abundant mast cells in the clinically normal skin of these patients. A congenitally abnormal skin was more easily acted on. Some toxin apparently was the cause of this affection, and it probably did not act on normal skin. Its nature and mode of action were unknown.

Personal Observations on Two Thousand Cases of Skin Disease in the Negro.—Dr. HENRY H. HAZEN of Washington, D. C., said that the skin diseases more prevalent among negroes than whites were dermatitis papillaris capillitti, keloids, dry seborrhea, syphillis, tinea tonsorans, urticaria and vitiligo. Alopecia areata, cancer, eczema, erythema, furuncles and boils, angiomata and nevi, pediculus capitis and psoriasis were less prevalent among negroes than among whites.

Diffuse Erythematous Lupus Treated with Tuberculin.—Dr. AUGUST RAVOGLI of Cincinnati reported the case of a female, aged twenty-four, who exhibited a typical clinical picture of this disease, with a positive Moro and a negative Wassermann. Local treatment proving ineffective, he resorted to the use of tuberculin T.R, injecting 1/100 of a milligram into the back. The following day the patient's fever was 104°, pulse 108, respiration 34. Her face was red and edematous; the eyes closed. In many places of eruption blisters had formed, leaving extended excoriations discharging serum. Fever continued, ranging from 101° to 105°, with low delirium, and less than two weeks after the injection the patient died. The clinical diagnosis was acute miliary tuberculosis. A necropsy was refused. He believed that for diagnostic purposes, used locally, tuberculin was safe, but for injection it was dangerous. He was sure that in his case it aroused into acuity a dormant tuberculosis, the patient dying from a tubercular septicemia. Tuberculin for treatment, even in the smallest dose, was a dangerous remedy.
